INACTION Systems programming concepts

Tim McNamara

and techniques

Raw Pointer

The cousins *mut T and *const T are the free radicals of the pointer world. Lightning fast, but wildly unsafe.

Powers • Speed

- Weaknesses • Unsafe
- · Can interact with the outside world

Box<T>

Store anything in a box. Accepts almost any type for long-term storage. The workhorse of a new, safe programming era.

Weaknesses

· Size increase

Powers

· Store a value in central storage in a location called "the heap"

Rc<T>

The reference counted pointer, Rc<T> is Rust's competent, yet miserly bookkeeper. It knows who has borrowed what and when.

Powers

- Weaknesses · Shared access · Size increase to values
 - Runtime cost
 - Not threadsafe

Arc<T>

Arc<T> is Rust's ambassador. It can share values across threads, guaranteeing that these will not interfere with each other.

Powers

- Weaknesses · Shared access · Size increase to values
 - · Runtime cost
- Threadsafe

Cell<T>

An expert in metamorphosis, Cell<T> confers the ability to mutate immutable values.

Powers · Interior mutability

Weaknesses

· Size increase Performance

RefCell<T>

Performs mutation on immutable references with RefCel<T>. Its mind-bending powers come with some costs.

Powers

· Interior mutability · Can be nested within Rc and Arc.

Weaknesses

which only accept immutable refs

- · Size increase
- · Lack of compiletime guarantees

Cow<T>

Why write something down when you only need to read it? Perhaps you only want to make modifications. This is the role of Cow (copy on write).

access is used

Weaknesses Avoids writes Possible size when only read increase

String

Acting as a guide on how to deal with the uncertainties of user input, String shows us how to build safe abstractions.

Grows dynamically as required

Weaknesses · Can over

- · Guarantees correct encoding at runtime

Vec<T>

Your program's main storage system. Vec<T> keeps your data orderly as values are created and destroyed.

· Grows dynamically

Weaknesses Can over allocate size

RawVec<T>

The bedrock of Vec<T> and other dynamically sized types. Understands how to provide a home for your data as needed.

Weaknesses · Grows dynamically · Not directly

applicable from

your code

- · Works with the
- memory allocator to find space

Unique<T>

Sole owner of a value, a unique pointer is guaranteed to possess full control.

Powers

Weaknesses

· Base for types · Not appropriate such as Strings, requiring exclusive code directly possession of values.

Shared<T>

Sharing ownership is hard. Shared<T> makes life a little bit easier.

Powers · Shared ownership

Weaknesses

- · Can align memory to T's width, even when empty
- · Not appropriate code directly

1 Introducing Rust

- 1.1 Where is Rust used? 2
- 1.2 Advocating for Rust at work 3
- 1.3 A taste of the language 4

 Cheating your way to "Hello, world!" 5 Your first Rust program 7
- 1.4 Downloading the book's source code 8
- 1.5 What does Rust look and feel like? 8
- 1.6 What is Rust? 11

 Goal of Rust: Safety 12 Goal of Rust: Productivity 16

 Goal of Rust: Control 18
- 1.7 Rust's big features 19

 Performance 19 Concurrency 20 Memory efficiency 20

viii CONTENTS

1.8 Downsides of Rust 20

	Cyclic data structures 20 • Compile times 20 • Strictness 21 Size of the language 21 • Hype 21
1.9	TLS security case studies 21
	Heartbleed 21 • Goto fail; 22
1.10	Where does Rust fit best? 23
	Command-line utilities 23 • Data processing 24 • Extending applications 24 • Resource-constrained environments 24 Server-side applications 25 • Desktop applications 25 Desktop 25 • Mobile 25 • Web 26 • Systems programming 26
1.11	Rust's hidden feature: Its community 26
1.12	Rust phrase book 26
	LANGUAGE DISTINCTIVES29 uage foundations 31
2.1	Creating a running program 33 Compiling single files with rustc 33 • Compiling Rust projects with cargo 33
2.2	A glance at Rust's syntax 34
	Defining variables and calling functions 35
2.3	Numbers 36
	Integers and decimal (floating-point) numbers 36 • Integers with base 2, base 8, and base 16 notation 37 • Comparing numbers 38 • Rational, complex numbers, and other numeric types 43
2.4	Flow control 45
	For: The central pillar of iteration 45 • Continue: Skipping the rest of the current iteration 47 • While: Looping until a condition changes its state 47 • Loop: The basis for Rust's looping constructs 48 • Break: Aborting a loop 48 • If, if else, and else: Conditional branching 49 • Match: Type-aware pattern matching 51
2.5	Defining functions 52
2.6	Using references 53
2.7	Project: Rendering the Mandelbrot set 54

CONTENTS ix

2.8	Advanced function definitions 56 Explicit lifetime annotations 56 • Generic functions 58
2.9	Creating grep-lite 60
2.10	Making lists of things with arrays, slices, and vectors 63
	Arrays 64 • Slices 65 • Vectors 66
2.11	Including third-party code 67
	Adding support for regular expressions 68 • Generating the third- party crate documentation locally 69 • Managing Rust toolchains with rustup 70
2.12	Supporting command-line arguments 70
2.13	Reading from files 72
2.14	Reading from stdin 74
Comp	ound data types 77
3.1	Using plain functions to experiment with an API 78
3.2	Modeling files with struct 80
3.3	Adding methods to a struct with impl 84
	Simplifying object creation by implementing new() 84
3.4	Returning errors 87
	Modifying a known global variable 87 • Making use of the Result return type 92
3.5	Defining and making use of an enum 95
	Using an enum to manage internal state 96
3.6	Defining common behavior with traits 98
	Creating a Read trait 98 • Implementing std::fmt::Display for your own types 99
3.7	Exposing your types to the world 102
	Protecting private data 102
3.8	Creating inline documentation for your projects 103
	Using rustdoc to render docs for a single source file 104 Using cargo to render docs for a crate and its dependencies 104
Lifetii	mes, ownership, and borrowing 107
4.1	Implementing a mock CubeSat ground station 108
	Encountering our first lifetime issue 110 • Special behavior of primitive types 112

12.1	O A note on applying these techniques to platforms without signals 417
12.1	1 Revising exceptions 417
	index 419

preface

No one knows whether reading a technical book is going to be worth the effort. These books can be expensive, dull, and poorly written. Even worse, there's a good chance that you won't learn anything. Luckily, this book is written by someone who understands that.

This book's first aim is to teach you Rust. *Rust in Action* presents large, working projects to promote your learning. Over the course of the book, you'll write a database, a CPU emulator, an operating system kernel, and several other interesting projects. You'll even dabble with generative art. Each project is designed to enable you to explore the Rust programming language at your own pace. For those readers who know little Rust, there are many opportunities to expand the projects in whatever direction you choose.

There is more to learning a programming language than studying its syntax and semantics, however. You are also joining a community. Unfortunately, established communities can create invisible barriers for new entrants because of their shared knowledge, jargon, and practices.

One such barrier for many new Rust programmers is the concept of systems programming. Lots of programmers come to Rust without a background in that area. To compensate for this, *Rust in Action* has a second aim—to teach you systems programming. And, among other topics, you'll learn about how memory, digital time-keeping, and device drivers work in the book's 12 chapters. I hope this enables you to feel more comfortable when becoming a member of the Rust community. And we need you!

xvi PREFACE

Our societies depend on software, yet critical security holes are accepted as normal and, perhaps, inevitable. Rust demonstrates that these are neither. Moreover, our computers are filled with bloated, energy-intensive applications. Rust provides a viable alternative for developing software that is less demanding on these finite resources.

Rust in Action is about empowerment. This book's ultimate objective is to convince you of that. Rust is not reserved for a select group of experts. It is a tool that's available for everyone. Well done for making it this far through your learning journey; it's my pleasure to take you a few more steps.

acknowledgments

Thank you to Katie for preventing me from collapsing and for picking me up when I fell down anyway. Thanks also to Florence and Octavia for your hugs and smiles, even when Dad was unable to play because he was writing.

I'm indebted to so many that it feels unfair to list only a select few. There are many members of the Rust community who have supported the book's development. Thousands of readers submitted corrections, questions, and suggestions via the liveBook during the book's development. Every contribution has helped me refine the text. Thank you.

I'm especially grateful to a small number of readers, many of whom have become friends. To Aï Maiga, Ana Hobden, Andrew Meredith, Andréy Lesnikóv, Andy Grove, Arturo J. Pérez, Bruce Mitchener, Cecile Tonglet, Daniel Carosone, Eric Ridge, Esteban Kuber, Florian Gilcher, Ian Battersby, Jane Lusby, Javier Viola, Jonathan Turner, Lachezar Lechev, Luciano Mammino, Luke Jones, Natalie Bloomfield, Oleksandr Kaleniuk, Olivia Ifrim, Paul Faria, Paul J. Symonds, Philipp Gniewosz, Rod Elias, Stephen Oates, Steve Klabnik, Tannr Allard, Thomas Lockney, and William Brown; interacting with you over the last four years has been a special privilege.

To the book's reviewers, I extend my warm thanks to Afshin Mehrabani, Alastair Smith, Bryce Darling, Christoffer Fink, Christopher Haupt, Damian Esteban, Federico Hernandez, Geert Van Laethem, Jeff Lim, Johan Liseborn, Josh Cohen, Konark Modi, Marc Cooper, Morgan Nelson, Ramnivas Laddad, Riccardo Moschetti, Sanket Naik, Sumant Tambe, Tim van Deurzen, Tom Barber, Wade Johnson, William Brown, William Wheeler, and Yves Dorfsman. All of your comments were read. Many of the

improvements in the latter stages of the book's development are owed to your thoughtful feedback.

Two team members at Manning deserve special credit for their patience, professionalism, and positivity: Elesha Hyde and Frances Buran have skillfully guided the book through many, many drafts.

Thank you also to the rest of the development editors, including Bert Bates, Jerry Kuch, Mihaela Batinić, Rebecca Rinehart, René van den Berg, and Tim van Deurzen. My thanks also extends to the production editors, including Benjamin Berg, Deirdre Hiam, Jennifer Houle, and Paul Wells.

Rust in Action had 16 releases during its MEAP process, and these would have been impossible without the support of many. Thank you to Aleksandar Dragosavljević, Ana Romac, Eleonor Gardner, Ivan Martinović, Lori Weidert, Marko Rajkovic, Matko Hrvatin, Mehmed Pasic, Melissa Ice, Mihaela Batinic, Owen Roberts, Radmila Ercegovac, and Rejhana Markanovic.

Thanks also to the members of the marketing team, including Branko Latincic, Candace Gillhoolley, Cody Tankersley, Lucas Weber, and Stjepan Jureković. You've been a tremendous source of encouragement for me.

The wider Manning team has also been very responsive and helpful. To Aira Dučić, Andrew Waldron, Barbara Mirecki, Branko Latincic, Breckyn Ely, Christopher Kaufmann, Dennis Dalinnik, Erin Twohey, Ian Hough, Josip Maras, Julia Quinn, Lana Klasic, Linda Kotlyarsky, Lori Kehrwald, and Melody Dolab, thank you for your assistance during the book's development. And to Mike Stephens, thanks for kicking this whole life-changing process off. You warned me that it would be hard. You were right.

about this book

Rust in Action is primarily intended for people who may have explored Rust's free material online, but who then have asked themselves, "What's next?" This book contains dozens of examples that are interesting and can be extended as creativity and time allow. Those examples allow the book's 12 chapters to cover a productive subset of Rust and many of the ecosystem's most important third-party libraries.

The code examples emphasize accessibility to beginners over elegant, idiomatic Rust. If you are already a knowledgeable Rust programmer, you may find yourself disagreeing with some style decisions in the examples. I hope that you will tolerate this for the sake of learners.

Rust in Action is not intended as a comprehensive reference text book. There are parts of the languages and standard library that have been omitted. Typically, these are highly specialized and deserve specific treatment. Instead, this book aims to provide readers with enough basic knowledge and confidence to learn specialized topics when necessary. Rust in Action is also unique from the point of view of systems programming books as almost every example works on Microsoft Windows.

Who should read this book

Anyone who is interested in Rust, who learns by applying practical examples, or who is intimidated by the fact that Rust is a systems programming language will enjoy *Rust in Action*. Readers with prior programming experience will benefit most as some computer programming concepts are assumed.

How this book is organized: A roadmap

Rust in Action has two parts. The first introduces Rust's syntax and some of its distinctive characteristics. The second part applies the knowledge gained in part one to several projects. In each chapter, one or two new Rust concepts are introduced. That said, part 1 provides a quick-fire introduction to Rust:

- Chapter 1, "Introducing Rust," explains why Rust exists and how to get started programming with it.
- Chapter 2, "Language foundations," provides a solid base of Rust syntax. Examples include a Mandelbrot set renderer and a grep clone.
- Chapter 3, "Compound data types," explains how to compose Rust data types and its error-handling facilities.
- Chapter 4, "Lifetimes, ownership, and borrowing," discusses the mechanisms for ensuring that accessing data is always valid.

Part 2 applies Rust to introductory systems programming areas:

- Chapter 5, "Data in Depth," covers how information is represented in digital computers with a special emphasis on how numbers are approximated. Examples include a bespoke number format and a CPU emulator.
- Chapter 6, "Memory," explains the terms references, pointers, virtual memory, stack, and heap. Examples include a memory scanner and a generative art project.
- Chapter 7, "Files and storage," explains the process for storing data structures into storage devices. Examples include a hex dump clone and a working database.
- Chapter 8, "Networking," provides an explanation of how computers communicate by reimplementing HTTP multiple times, stripping away a layer of abstraction each time.
- Chapter 9, "Time and timekeeping," explores the process for keeping track of time within a digital computer. Examples include a working NTP client.
- Chapter 10, "Processes, threads, and containers," explains processes, threads, and related abstractions. Examples include a turtle graphics application and a parallel parser.
- Chapter 11, "Kernel," describes the role of the operating system and how computers boot up. Examples include compiling your own bootloader and an operating system kernel.
- Chapter 12, "Signals, interrupts, and exceptions," explains how the external world communicates with the CPU and operating systems.

The book is intended to be read linearly. Latter chapters assume knowledge taught in earlier ones. However, projects from each chapter are standalone. Therefore, you are welcome to jump backward and forward if there are topics that you would like to cover.

About the code

The code examples in *Rust in Action* are written with the 2018 edition of Rust and have been tested with Windows and Ubuntu Linux. No special software is required outside of a working Rust installation. Installation instructions are provided in chapter 2.

This book contains many examples of source code both in numbered listings and inline with normal text. In both cases, source code is formatted in a fixed-width font, like this, to separate it from ordinary text. Sometimes code is also in **bold** to highlight code that has changed from the previous steps in the chapter, such as when a new feature is added to an existing line of code.

In many cases, the original source code has been reformatted; we've added line breaks and reworked indentation to accommodate the available page space in the book. In rare cases, even this was not enough, and listings include line-continuation markers (\Rightarrow). Additionally, comments in the source code have often been removed from the listings when the code is described in the text. Code annotations accompany many of the listings, highlighting important concepts.

liveBook discussion forum

Purchase of *Rust in Action* includes free access to a private web forum run by Manning Publications where you can make comments about the book, ask technical questions, and receive help from the author and from other users:

- To access the forum, go to https://livebook.manning.com/book/rust-in-action/welcome/v-16/.
- You can also learn more about Manning's forums and the rules of conduct at this location: https://livebook.manning.com/#!/discussion.

Manning's commitment to our readers is to provide a venue where a meaningful dialogue between individual readers and between readers and the author can take place. It is not a commitment to any specific amount of participation on the part of the author, whose contribution to the forum remains voluntary (and unpaid). We suggest you try asking the author some challenging questions lest his interest stray! The forum and the archives of previous discussions will be accessible from the publisher's website as long as the book is in print.

Other online resources

Tim can be found on social media as @timClicks. His primary channels are Twitter (https://twitter.com/timclicks), YouTube (https://youtube.com/c/timclicks), and Twitch (https://twitch.tv/timclicks). You are also welcome to join his Discord server at https://discord.gg/vZBX2bDa7W.

about the author

TIM MCNAMARA learned programming to assist with humanitarian relief projects around the world from his home in New Zealand. Over the last 15 years, Tim has become an expert in text mining, natural language processing, and data engineering. He is the organizer of Rust Wellington and hosts regular Rust programming tutorials in person and online via Twitch and YouTube.

about the cover illustration

The figure on the cover of *Rust in Action* is captioned "Le maitre de chausson" or "The boxer." The illustration is taken from a collection of works by many artists, edited by Louis Curmer and published in Paris in 1841. The title of the collection is *LesFrançais peints par eux-mêmes*, which translates as *The French People Painted by Themselves*. Each illustration is finely drawn and colored by hand, and the rich variety of drawing in the collection reminds us vividly of how culturally apart the world's regions, towns, villages, and neighborhoods were just 200 years ago. Isolated from each other, people spoke different dialects and languages. In the streets or in the countryside, it was easy to identify where they lived and what their trade or station in life was just by their dress.

Dress codes have changed since then and the diversity by region, so rich at the time, has faded away. It is now hard to tell apart the inhabitants of different continents, let alone different towns or regions. Perhaps we have traded cultural diversity for a more varied personal life—certainly for a more varied and fast-paced technological life.

At a time when it is hard to tell one computer book from another, Manning celebrates the inventiveness and initiative of the computer business with book covers based on the rich diversity of regional life of two centuries ago, brought back to life by pictures from collections such as this one.

Introducing Rust

This chapter covers

- Introducing Rust's features and goals
- Exposing Rust's syntax
- Discussing where to use Rust and when to avoid it
- Building your first Rust program
- Explaining how Rust compares to object-oriented and wider languages

Welcome to Rust—the empowering programming language. Once you scratch its surface, you will not only find a programming language with unparalleled speed and safety, but one that is enjoyable enough to use every day.

When you begin to program in Rust, it's likely that you will want to continue to do so. And this book, *Rust in Action*, will build your confidence as a Rust programmer. But it will not teach you how to program from the beginning. This book is intended to be read by people who are considering Rust as their next language and for those who enjoy implementing practical working examples. Here is a list of some of the larger examples this book includes:

- Mandelbrot set renderer
- A grep clone

- CPU emulator
- Generative art.
- A database
- HTTP, NTP, and hexdump clients
- LOGO language interpreter
- Operating system kernel

As you may gather from scanning through that list, reading this book will teach you more than just Rust. It also introduces you to *systems programming* and *low-level programming*. As you work through *Rust in Action*, you'll learn about the role of an operating system (OS), how a CPU works, how computers keep time, what pointers are, and what a data type is. You will gain an understanding of how the computer's internal systems interoperate. Learning more than syntax, you will also see why Rust was created and the challenges that it addresses.

1.1 Where is Rust used?

Rust has won the "most loved programming language" award in Stack Overflow's annual developer survey every year in 2016-2020. Perhaps that's why large technology leaders such as the following have adopted Rust:

- Amazon Web Services (AWS) has used Rust since 2017 for its serverless computing offerings, AWS Lambda and AWS Fargate. With that, Rust has gained further inroads. The company has written the Bottlerocket OS and the AWS Nitro System to deliver its Elastic Compute Cloud (EC2) service.¹
- Cloudflare develops many of its services, including its public DNS, serverless computing, and packet inspection offerings with Rust.²
- Dropbox rebuilt its backend warehouse, which manages exabytes of storage, with Rust.³
- Google develops parts of Android, such as its Bluetooth module, with Rust. Rust is also used for the crosvm component of Chrome OS and plays an important role in Google's new operating system, Fuchsia.⁴
- Facebook uses Rust to power Facebook's web, mobile, and API services, as well as parts of HHVM, the HipHop virtual machine used by the Hack programming language.⁵
- Microsoft writes components of its Azure platform including a security daemon for its Internet of Things (IoT) service in Rust.⁶

⁶ See https://github.com/Azure/iotedge/tree/master/edgelet.

- Mozilla uses Rust to enhance the Firefox web browser, which contains 15 million lines of code. Mozilla's first two Rust-in-Firefox projects, its MP4 metadata parser and text encoder/decoder, led to overall performance and stability improvements.
- GitHub's npm, Inc., uses Rust to deliver "upwards of 1.3 billion package down-loads per day."
- Oracle developed a container runtime with Rust to overcome problems with the Go reference implementation.⁸
- Samsung, via its subsidiary SmartThings, uses Rust in its Hub, which is the firmware backend for its Internet of Things (IoT) service.

Rust is also productive enough for fast-moving startups to deploy it. Here are a few examples:

- Sourcegraph uses Rust to serve syntax highlighting across all of its languages.⁹
- Figma employs Rust in the performance-critical components of its multi-player server.¹⁰
- Parity develops its client to the Ethereum blockchain with Rust.¹¹

1.2 Advocating for Rust at work

What is it like to advocate for Rust at work? After overcoming the initial hurdle, it tends to go well. A 2017 discussion, reprinted below, provides a nice anecdote. One member of Google's Chrome OS team discusses what it was like to introduce the language to the project:¹²

```
indy on Sept 27, 2017
Is Rust an officially sanctioned language at Google?
```

zaxcellent on Sept 27, 2017

Author here: Rust is not officially sanctioned at Google, but there are pockets of folks using it here. The trick with using Rust in this component was convincing my coworkers that no other language was right for job, which I believe to be the case in this instance.

That being said, there was a ton of work getting Rust to play nice within the Chrome OS build environment. The Rust folks have been super helpful in answering my questions though.

```
ekidd on Sept 27, 2017 > The trick with using Rust in this component was convincing my
```

> coworkers that no other language was right for job, which I believe
> to be the case in this instance.

I ran into a similar use case in one of my own projects—a vobsub subtitle decoder, which parses complicated binary data, and which I someday want to run as web service. So obviously, I want to ensure that there are no vulnerabilities in my code.

I wrote the code in Rust, and then I used 'cargo fuzz' to try and find vulnerabilities. After running a billion(!) fuzz iterations, I found 5 bugs (see the 'vobsub' section of the trophy case for a list https://github.com/rust-fuzz/trophy-case).

Happily, not _one_ of those bugs could actually be escalated into an actual exploit. In each case, Rust's various runtime checks successfully caught the problem and turned it into a controlled panic. (In practice, this would restart the web server cleanly.)

So my takeaway from this was that whenever I want a language (1) with no GC, but (2) which I can trust in a security-critical context, Rust is an excellent choice. The fact that I can statically link Linux binaries (like with Go) is a nice plus.

Manishearth on Sept 27, 2017

- > Happily, not one of those bugs could actually be escalated into
- > an actual exploit. In each case, Rust's various runtime checks
- > successfully caught the problem and turned it into a controlled
- > panic.

This has been more or less our experience with fuzzing rust code in firefox too, fwiw. Fuzzing found a lot of panics (and debug assertions / "safe" overflow assertions). In one case it actually found a bug that had been under the radar in the analogous Gecko code for around a decade.

From this excerpt, we can see that language adoption has been "bottom up" by engineers looking to overcome technical challenges in relatively small projects. Experience gained from these successes is then used as evidence to justify undertaking more ambitious work.

In the time since late 2017, Rust has continued to mature and strengthen. It has become an accepted part of Google's technology landscape, and is now an officially sanctioned language within the Android and Fuchsia operating systems.

1.3 A taste of the language

This section gives you a chance to experience Rust firsthand. It demonstrates how to use the compiler and then moves on to writing a quick program. We tackle full projects in later chapters.

NOTE To install Rust, use the official installers provided at https://rustup.rs/.

1.3.1 Cheating your way to "Hello, world!"

The first thing that most programmers do when they reach for a new programming language is to learn how to print "Hello, world!" to the console. You'll do that too, but with flair. You'll verify that everything is in working order *before* you encounter annoying syntax errors.

If you use Windows, open the Rust command prompt that is available in the Start menu after installing Rust. Then execute this command:

```
C:\> cd %TMP%
```

If you are running Linux or macOS, open a Terminal window. Once open, enter the following:

```
$ cd $TMP
```

From this point forward, the commands for all operating systems should be the same. If you installed Rust correctly, the following three commands will display "Hello, world!" on the screen (as well as a bunch of other output):

```
$ cargo new hello
$ cd hello
$ cargo run
```

Here is an example of what the entire session looks like when running cmd.exe on MS Windows:

And on Linux or macOS, your console would look like this:

```
Finished dev [unoptimized + debuginfo] target(s) in 0.26s
  Running `target/debug/hello`
Hello, world!
```

If you have made it this far, fantastic! You have run your first Rust code without needing to write any Rust. Let's take a look at what just happened.

Rust's cargo tool provides both a build system and a package manager. That means cargo knows how to convert your Rust code into executable binaries and also can manage the process of downloading and compiling the project's dependencies.

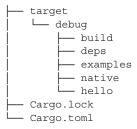

cargo new creates a project for you that follows a standard template. The tree command can reveal the default project structure and the files that are created after issuing cargo new:

All Rust projects created with cargo have the same structure. In the base directory, a file called Cargo.toml describes the project's metadata, such as the project's name, its version, and its dependencies. Source code appears in the src directory. Rust source code files use the .rs filename extension. To view the files that cargo new creates, use the tree command.

The next command that you executed was cargo run. This line is much simpler to grasp, but cargo actually did much more work than you realized. You asked cargo to run the project. As there was nothing to actually run when you invoked the command, it decided to compile the code in debug mode on your behalf to provide maximal error information. As it happens, the src/main.rs file always includes a "Hello, world!" stub. The result of that compilation was a file called hello (or hello.exe). The hello file was executed, and the result printed to your screen.

Executing cargo run has also added new files to the project. We now have a Cargo.lock file in the base of our project and a target/ directory. Both that file and the directory are managed by cargo. Because these are artifacts of the compilation process, we won't need to touch these. Cargo.lock is a file that specifies the exact version numbers of all the dependencies so that future builds are reliably built the same way until Cargo.toml is modified.

Running tree again reveals the new structure created by invoking cargo run to compile the hello project:

For getting things up and running, well done! Now that we've cheated our way to "Hello, World!", let's get there via the long way.

1.3.2 Your first Rust program

For our first program, we want to write something that outputs the following text in multiple languages:

```
Hello, world!
Grüß Gott!
ハロー・ワールド
```

You have probably seen the first line in your travels. The other two are there to highlight a few of Rust's features: easy iteration and built-in support for Unicode. For this program, we'll use cargo to create it as before. Here are the steps to follow:

- Open a console prompt.
- 2 Run cd %TMP% on MS Windows; otherwise cd \$TMP.
- 3 Run cargo new hello2 to create a new project.
- 4 Run cd hello2 to move into the project's root directory.
- 5 Open the file src/main.rs in a text editor.
- 6 Replace the text in that file with the text in listing 1.1.

The code for the following listing is in the source code repository. Open ch1/ch1-hello2/src/hello2.rs.

Listing 1.1 "Hello World!" in three languages

```
The exclamation mark indicates the use of
                                                                          Assignment in Rust, more
                            a macro, which we'll discuss shortly.
                                                                          properly called variable
                                                                          binding, uses the let keyword.
                1 fn greet world() {
    Array
                     println!("Hello, world!");
                                                                             Unicode support is
   literals
                3
                      let southern germany = "Gruß Gott!";
                                                                             provided out of the box.
use square
                    let japan = "ハロー・ワールド";
                4
 brackets.
               5
                    let regions = [southern germany, japan];
                                                                         Many types can have an iter()
                6
                      for region in regions.iter() {
                                                                         method to return an iterator.
                7
                               println!("{}", &region); <-</pre>
                                                                    The ampersand "borrows"
                8
                                                                    region for read-only access.
                9 }
```

```
10
11 fn main() {
12    greet_world();
13 }

Calls a function. Note that parentheses follow the function name.
```

Now that src/main.rs is updated, execute cargo run from the hello2/ directory. You should see three greetings appear after some output generated from cargo itself:

```
$ cargo run
   Compiling hello2 v0.1.0 (/path/to/ch1/ch1-hello2)
   Finished dev [unoptimized + debuginfo] target(s) in 0.95s
   Running `target/debug/hello2`
Hello, world!
Grüß Gott!
ハロー・フールド
```

Let's take a few moments to touch on some of the interesting elements of Rust from listing 1.1.

One of the first things that you are likely to notice is that strings in Rust are able to include a wide range of characters. Strings are guaranteed to be encoded as UTF-8. This means that you can use non-English languages with relative ease.

The one character that might look out of place is the exclamation mark after println. If you have programmed in Ruby, you may be used to thinking that it is used to signal a destructive operation. In Rust, it signals the use of a *macro*. Macros can be thought of as fancy functions for now. These offer the ability to avoid boilerplate code. In the case of println!, there is a lot of type detection going on under the hood so that arbitrary data types can be printed to the screen.

1.4 Downloading the book's source code

In order to follow along with the examples in this book, you might want to access the source code for the listings. For your convenience, source code for every example is available from two sources:

- https://manning.com/books/rust-in-action
- https://github.com/rust-in-action/code

1.5 What does Rust look and feel like?

Rust is the programming language that allows Haskell and Java programmers to get along. Rust comes close to the high-level, expressive feel of dynamic languages like Haskell and Java while achieving low-level, bare-metal performance.

We looked at a few "Hello, world!" examples in section 1.3, so let's try something slightly more complex to get a better feel for Rust's features. Listing 1.2 provides a quick look at what Rust can do for basic text processing. The source code for this listing is in the ch1/ch1-penguins/src/main.rs file. Some features to notice include

- Common control flow mechanisms—This includes for loops and the continue keyword.
- Method syntax—Although Rust is not object-oriented as it does not support inheritance, it carries over this feature of object-oriented languages.
- *Higher-order programming*—Functions can both accept and return functions. For example, line 19 (.map(|field| field.trim())) includes a *closure*, also known as an *anonymous function* or *lambda function*.
- *Type annotations*—Although relatively rare, these are occasionally required as a hint to the compiler (for example, see line 27 beginning with if let Ok (length)).
- *Conditional compilation*—In the listing, lines 21–24 (if cfg! (...);) are not included in release builds of the program.
- *Implicit return*—Rust provides a return keyword, but it's usually omitted. Rust is an *expression-based language*.

Listing 1.2 Example of Rust code showing some basic processing of CSV data

```
1 fn main() {
                                                          Executable projects
               2
                   let penguin data = "\
                                                          require a main()
                  common name, length (cm)
               3
                                                          function.
               4 Little penguin,33
                  Yellow-eyed penguin,65
               5
                                                        Escapes the trailing
                   Fiordland penguin, 60
               6
                                                      newline character
               7
                    Invalid, data
               8
               9
              10
                    let records = penguin data.lines();
                                                                           Skips header row
              11
                                                                           and lines with
                  for (i, record) in records.enumerate() {
              12
                                                                           only whitespace
              13
                    if i == 0 || record.trim().len() == 0 {
              14
                        continue;
              15
                                                                Starts with a
   Splits
                                                                line of text
  record
              17
                      let fields: Vec< > = record
                     .split(',')
into fields
                                                                   Trims whitespace
              18
                      .map(|field| field.trim())
                                                                   of each field
              19
              20
                       .collect();
 Builds a
                                                                 cfg! checks configuration at compile time.
                    if cfg!(debug_assertions) {
              21
collection
                  eprintln!("debug: {:?} -> {:?}",
              22
 of fields
              23
                              record, fields);
                                                                 eprintln! prints to
              24
                                                                 standard error (stderr).
              25
              26
                      let name = fields[0];
              2.7
                      if let Ok(length) = fields[1].parse::<f32>() {
                                                                                     Attempts to parse
                          println!("{}, {}cm", name, length);
                                                                                     field as a floating-
              29
                                                                                    point number
              30
                                                           println! prints to
                                                       standard out (stdout).
              31 }
```

Listing 1.2 might be confusing to some readers, especially those who have never seen Rust before. Here are some brief notes before moving on:

- On line 17, the fields variable is annotated with the type Vec<_>. Vec is shorthand for _vector_, a collection type that can expand dynamically. The underscore (_) instructs Rust to infer the type of the elements.
- On lines 22 and 28, we instruct Rust to print information to the console. The println! macro prints its arguments to standard out (stdout), whereas eprintln! prints to standard error (stderr).

Macros are similar to functions except that instead of returning data, these return code. Macros are often used to simplify common patterns.

eprintln! and println! both use a string literal with an embedded minilanguage in their first argument to control their output. The {} placeholder tells Rust to use a programmer-defined method to represent the value as a string rather than the default representation available with {:?}.

• Line 27 contains some novel features. if let Ok(length) = fields[1].parse ::<f32>() reads as "attempt to parse fields[1] as a 32-bit floating-point number and, if that is successful, then assign the number to the length variable."

The if let construct is a concise method of conditionally processing data that also provides a local variable assigned to that data. The parse() method returns Ok(T) (where T stands for any type) when it can successfully parse the string; otherwise, it returns Err(E) (where E stands for an error type). The effect of if let Ok(T) is to skip any error cases like the one that's encountered while processing the line Invalid, data.

When Rust is unable to infer the types from the surrounding context, it will ask for you to specify those. The call to parse() includes an inline type annotation as parse::<f32>().

Converting source code into an executable file is called *compiling*. To compile Rust code, we need to install the Rust compiler and run it against the source code. To compile listing 1.2, follow these steps:

- 1 Open a console prompt (such as cmd.exe, PowerShell, Terminal, or Alacritty).
- 2 Move to the ch1/ch1-penguins directory (not ch1/ch1-penguins/src) of the source code you downloaded in section 1.4.
- **3** Execute cargo run. Its output is shown in the following code snippet:

\$ cargo run

```
Compiling ch1-penguins v0.1.0 (../code/ch1/ch1-penguins)
   Finished dev [unoptimized + debuginfo] target(s) in 0.40s
   Running `target/debug/ch1-penguins`

dbg: " Little penguin, 33" -> ["Little penguin", "33"]
Little penguin, 33cm

dbg: " Yellow-eyed penguin,65" -> ["Yellow-eyed penguin", "65"]

Yellow-eyed penguin, 65cm

dbg: " Fiordland penguin,60" -> ["Fiordland penguin", "60"]

Fiordland penguin, 60cm

dbg: " Invalid,data" -> ["Invalid", "data"]
```

What is Rust?

You probably noticed the distracting lines starting with dbg:. We can eliminate these by compiling a *release build* using cargo's --release flag. This conditional compilation functionality is provided by the cfg! (debug_assertions) { ... } block within lines 22–24 of listing 1.2. Release builds are much faster at runtime, but incur longer compilation times:

```
$ cargo run --release
   Compiling ch1-penguins v0.1.0 (.../code/ch1/ch1-penguins)
   Finished release [optimized] target(s) in 0.34s
   Running `target/release/ch1-penguins`
Little penguin, 33cm
Yellow-eyed penguin, 65cm
Fiordland penguin, 60cm
```

It's possible to further reduce the output by adding the -q flag to cargo commands. -q is shorthand for *quiet*. The following snippet shows what that looks like:

```
$ cargo run -q --release
Little penguin, 33cm
Yellow-eyed penguin, 65cm
Fiordland penguin, 60cm
```

Listing 1.1 and listing 1.2 were chosen to pack as many representative features of Rust into examples that are easy to understand. Hopefully these demonstrated that Rust programs have a high-level feel, paired with low-level performance. Let's take a step back from specific language features now and consider some of the thinking behind the language and where it fits within the programming language ecosystem.

1.6 What is Rust?

Rust's distinguishing feature as a programming language is its ability to prevent invalid data access at compile time. Research projects by Microsoft's Security Response Center and the Chromium browser project both suggest that issues relating to invalid data access account for approximately 70% of serious security bugs. Rust eliminates that class of bugs. It guarantees that your program is *memory-safe* without imposing any runtime costs.

Other languages can provide this level of safety, but these require adding checks that execute while your program is running, thus slowing it down. Rust manages to break out of this continuum, creating its own space as illustrated by figure 1.1.

Rust's distinguishing feature as a professional community is its willingness to explicitly include values into its decision-making process. This ethos of inclusion is pervasive. Public messaging is welcoming. All interactions within the Rust community are governed by its code of conduct. Even the Rust compiler's error messages are ridiculously helpful.

¹³ See the articles "We need a safer systems programming language," http://mng.bz/VdN5 and "Memory safety," http://mng.bz/xm7B for more information.

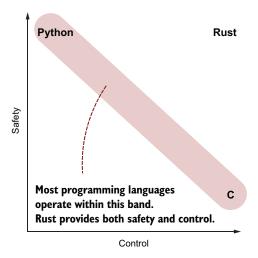

Figure 1.1 Rust provides both safety and control. Other languages have tended to trade one against the other.

Until late 2018, visitors to the Rust home page were greeted with the (technically heavy) message, "Rust is a systems programming language that runs blazingly fast, prevents segfaults, and guarantees thread safety." At that point, the community implemented a change to its wording to put its users (and its potential users) at the center (table 1.1).

Table 1.1 Rust slogans over time. As Rust has developed its confidence, it has increasingly embraced the idea of acting as a facilitator and supporter of everyone wanting to achieve their programming aspirations.

Until late 2018	From that point onward
"Rust is a systems programming language that runs blazingly fast, prevents segfaults, and guarantees thread safety."	"Empowering everyone to build reliable and efficient software."

Rust is labelled as a *systems programming language*, which tends to be seen as quite a specialized, almost esoteric branch of programming. However, many Rust programmers have discovered that the language is applicable to many other domains. Safety, productivity, and control are useful in all software engineering projects. Moreover, the Rust community's inclusiveness means that the language benefits from a steady stream of new voices with diverse interests.

Let's flesh out those three goals: safety, productivity, and control. What are these and why do these matter?

1.6.1 Goal of Rust: Safety

Rust programs are free from

 Dangling pointers—Live references to data that has become invalid over the course of the program (see listing 1.3) What is Rust?

 Data races—The inability to determine how a program will behave from run to run because external factors change (see listing 1.4)

- Buffer overflow—An attempt to access the 12th element of an array with only 6 elements (see listing 1.5)
- *Iterator invalidation*—An issue caused by something that is iterated over after being altered midway through (see listing 1.6)

When programs are compiled in debug mode, Rust also protects against *integer overflow*. What is integer overflow? Well, integers can only represent a finite set of numbers; these have a fixed-width in memory. Integer overflow is what happens when the integers hit their limit and flow over to the beginning again.

The following listing shows a dangling pointer. Note that you'll find this source code in the ch1/ch1-cereals/src/main.rs file.

Listing 1.3 Attempting to create a dangling pointer

```
1 #[derive(Debug)]
                                          Allows the println! macro
 2 enum Cereal {
                                         to print the Cereal enum
     Barley, Millet, Rice,
 4
       Rye, Spelt, Wheat,
                                   An enum (enumeration) is
 5 }
                                   a type with a fixed number
                                  of legal variants.
                                                           Initializes an empty
 7 fn main() {
                                                         vector of Cereal
   let mut grains: Vec<Cereal> = vec![];
 8
 9
     grains.push(Cereal::Rye);
                                                 Adds one item to
10
     drop(grains);
                                               the grains vector
     println!("{:?}", grains); <--
11
12 }
                                               Deletes grains
                        Attempts to access
                                             and its contents
                         the deleted value
```

Listing 1.3 contains a pointer within grains, which is created on line 8. Vec<Cereal> is implemented with an internal pointer to an underlying array. But the listing does not compile. An attempt to do so triggers an error message that complains about attempting to "borrow" a "moved" value. Learning how to interpret that error message and to fix the underlying error are topics for the pages to come. Here's the output from attempting to compile the code for listing 1.3:

\$ cargo run

Listing 1.4 shows an example of a data race condition. If you remember, this condition results from the inability to determine how a program behaves from run to run due to changing external factors. You'll find this code in the ch1/ch1-race/src/main.rs file.

Listing 1.4 Example of Rust preventing a race condition

If you are unfamiliar with the term *thread*, the upshot is that this code is not deterministic. It's impossible to know what value data will hold when main() exits. On lines 6 and 7 of the listing, two threads are created by calls to thread::spawn(). Each call takes a closure as an argument, denoted by vertical bars and curly braces (e.g., || {...}). The thread spawned on line 5 is attempting to set the data variable to 500, whereas the thread spawned on line 6 is attempting to set it to 1,000. Because the scheduling of threads is determined by the OS rather than the program, it's impossible to know if the thread defined first will be the one that runs first.

Attempting to compile listing 1.5 results in a stampede of error messages. Rust does not allow multiple places in an application to have write access to data. The code attempts to allow this in three places: once within the main thread running main() and once in each child thread created by thread::spawn(). Here's the compiler message:

\$ cargo run

What is Rust?

Listing 1.5 provides an example of a buffer overflow. A buffer overflow describes situations where an attempt is made to access items in memory that do not exist or that are illegal. In our case, an attempt to access fruit [4] results in the program crashing, as the fruit variable only contains three fruit. The source code for this listing is in the file ch1/ch1-fruit/src/main.rs.

Listing 1.5 Example of invoking a panic via a buffer overflow

```
1 fn main() {
2    let fruit = vec!['②', '&', '\\"];
3    let buffer_overflow = fruit[4];
5    assert_eq!(buffer_overflow, '\\")    assert_eq!() tests that arguments are equal.
Rust will cause a crash rather than assign an invalid memory location to a variable.

assert_eq!() tests that arguments are equal.
```

When listing 1.5 is compiled and executed, you'll encounter this error message:

```
$ cargo run
   Compiling ch1-fruit v0.1.0 (/rust-in-action/code/ch1/ch1-fruit)
   Finished dev [unoptimized + debuginfo] target(s) in 0.31s
   Running `target/debug/ch1-fruit`
thread 'main' panicked at 'index out of bounds:
   the len is 3 but the index is 4', src/main.rs:3:25
note: run with `RUST_BACKTRACE=1` environment variable
   to display a backtrace
```

The next listing shows an example of iterator invalidation, where an issue is caused by something that's iterated over after being altered midway through. The source code for this listing is in ch1/ch1-letters/src/main.rs.

Listing 1.6 Attempting to modify an iterator while iterating over it

```
for letter in letters {
    println!("{}", letter);
    letters.push(letter.clone());
    }
}

Copies each letter and appends it to the end of letters
```

Listing 1.6 fails to compile because Rust does not allow the letters variable to be modified within the iteration block. Here's the error message:

```
$ cargo run
   Compiling ch1-letters v0.1.0 (/rust-in-action/code/ch1/ch1-letters)
error[E0382]: borrow of moved value: `letters`
--> src/main.rs:8:7
2 | let mut letters = vec![
       ----- move occurs because `letters` has type
                     `std::vec::Vec<&str>`, which does not
                     implement the `Copy` trait
    for letter in letters {
6
                    `letters` moved due to this implicit call
                    to `.into iter()`
                    help: consider borrowing to avoid moving
                    into the for loop: `&letters`
       println!("{}", letter);
7 I
         letters.push(letter.clone());
^^^^^ value borrowed here after move
error: aborting due to previous error
For more information about this error, try `rustc --explain E0382`.
error: could not compile `ch1-letters`.
To learn more, run the command again with --verbose.
```

While the language of the error message is filled with jargon (*borrow, move, trait*, and so on), Rust has protected the programmer from stepping into a trap that many others fall into. And fear not—that jargon will become easier to understand as you work through the first few chapters of this book.

Knowing that a language is safe provides programmers with a degree of liberty. Because they know their program won't implode, they become much more willing to experiment. Within the Rust community, this liberty has spawned the expression *fear-less concurrency*.

1.6.2 Goal of Rust: Productivity

When given a choice, Rust prefers the option that is easiest for the developer. Many of its more subtle features are productivity boosts. But programmer productivity is a difficult concept to demonstrate through an example in a book. Let's start with something

What is Rust?

that can snag beginners—using assignment (=) within an expression that should use an equality (==) test:

```
1 fn main() {
2    let a = 10;
3
4    if a = 10 {
5        println!("a equals ten");
6    }
7 }
```

In Rust, the preceding code fails to compile. The Rust compiler generates the following message:

At first, "mismatched types" might feel like a strange error message to encounter. Surely we can test variables for equality against integers.

After some thought, it becomes apparent why the if test receives the wrong type. The if is not receiving an integer. It's receiving the result of an assignment. In Rust, this is the blank type: (). () is pronounced *unit.*¹⁴

When there is no other meaningful return value, expressions return (). As the following shows, adding a second equals sign on line 4 results in a working program that prints a equals ten:

```
1 fn main() {
2    let a = 10;
3    using a valid assignment operator (==) allows the program to compile.
5    println!("a equals ten");
6  }
7 }
```

¹⁴ The name *unit* reveals some of Rust's heritage as a descendant of the ML family of programming languages that includes OCaml and F#. The term stems from mathematics. Theoretically, a unit type only has a single value. Compare this with Boolean types that have two values, true or false, or strings that have an infinite number of valid values.

Rust has many ergonomic features. It offers generics, sophisticated data types, pattern matching, and closures. ¹⁵ Those who have worked with other ahead-of-time compilation languages are likely to appreciate Rust's build system and its comprehensive package manager: cargo.

At first glance, we see that cargo is a front end for rustc, the Rust compiler, but cargo provides several additional utilities including the following:

- cargo new creates a skeleton Rust project in a new directory (cargo init uses the current directory).
- cargo build downloads dependencies and compiles the code.
- cargo run executes cargo build and then also runs the resulting executable file
- cargo doc builds HTML documentation for every dependency in the current project.

1.6.3 Goal of Rust: Control

Rust offers programmers fine-grained control over how data structures are laid out in memory and their access patterns. While Rust uses sensible defaults that align with its "zero cost abstractions" philosophy, those defaults do not suit all situations.

At times, it is imperative to manage your application's performance. It might matter to you that data is stored in the *stack* rather than on the *heap*. Perhaps, it might make sense to add *reference counting* to create a shared reference to a value. Occasionally, it might be useful to create one's own type of *pointer* for a particular access pattern. The design space is large and Rust provides the tools to allow you to implement your preferred solution.

NOTE If terms such as *stack*, *heap*, and *reference counting* are new, don't put the book down! We'll spend lots of time explaining these and how they work together throughout the rest of the book.

Listing 1.7 prints the line a: 10, b: 20, c: 30, d: Mutex { data: 40 }. Each representation is another way to store an integer. As we progress through the next few chapters, the trade-offs related to each level become apparent. For the moment, the important thing to remember is that the menu of types is comprehensive. You are welcome to choose exactly what's right for your specific use case.

Listing 1.7 also demonstrates multiple ways to create integers. Each form provides differing semantics and runtime characteristics. But programmers retain full control of the trade-offs that they want to make.

¹⁵ If these terms are unfamiliar, do keep reading. These are explained throughout the book. They are language features that you will miss in other languages.

Listing 1.7 Multiple ways to create integer values

```
Integer on the heap, also
             1 use std::rc::Rc;
                                                         known as a boxed integer
             2 use std::sync::{Arc, Mutex};
Integer
                                                                 Boxed integer wrapped
on the
             4 fn main() {
                                                                 within a reference counter
 stack
             5
                    let a = 10;
                                                                          Integer wrapped in an atomic
             6
                    let b = Box::new(20);
                                                                          reference counter and protected
             7
                    let c = Rc::new(Box::new(30));
                                                                          by a mutual exclusion lock
             8
                   let d = Arc::new(Mutex::new(40));
                    println!("a: {:?}, b: {:?}, c: {:?}, d: {:?}", a, b, c, d);
             9
            10 }
```

To understand why Rust is doing something the way it is, it can be helpful to refer back to these three principles:

- The language's first priority is safety.
- Data within Rust is immutable by default.
- Compile-time checks are strongly preferred. Safety should be a "zero-cost abstraction."

1.7 Rust's big features

Our tools shape what we believe we can create. Rust enables you to build the software that you want to make, but were too scared to try. What kind of tool is Rust? Flowing from the three principles discussed in the last section are three overarching features of the language:

- Performance
- Concurrency
- Memory efficiency

1.7.1 Performance

Rust offers all of your computer's available performance. Famously, Rust does not rely on a garbage collector to provide its memory safety.

There is, unfortunately, a problem with promising you faster programs: the speed of your CPU is fixed. Thus, for software to run faster, it needs to do less. Yet, the language is large. To resolve this conflict, Rust pushes the burden onto the compiler.

The Rust community prefers a bigger language with a compiler that does more, rather than a simpler language where the compiler does less. The Rust compiler aggressively optimizes both the size and speed of your program. Rust also has some less obvious tricks:

• Cache-friendly data structures are provided by default. Arrays usually hold data within Rust programs rather than deeply nested tree structures that are created by pointers. This is referred to as data-oriented programming.

- The availability of a modern package manager (cargo) makes it trivial to benefit from tens of thousands of open source packages. C and C++ have much less consistency here, and building large projects with many dependencies is typically difficult.
- Methods are always dispatched statically unless you explicitly request dynamic dispatch.
 This enables the compiler to heavily optimize code, sometimes to the point of eliminating the cost of a function call entirely.

1.7.2 Concurrency

Asking a computer to do more than one thing at the same time has proven difficult for software engineers. As far as an OS is concerned, two independent threads of execution are at liberty to destroy each other if a programmer makes a serious mistake. Yet Rust has spawned the expression *fearless concurrency*. Its emphasis on safety crosses the bounds of independent threads. There is no global interpreter lock (GIL) to constrain a thread's speed. We explore some of the implications of this in part 2.

1.7.3 Memory efficiency

Rust enables you to create programs that require minimal memory. When needed, you can use fixed-size structures and know exactly how every byte is managed. Highlevel constructs, such as iteration and generic types, incur minimal runtime overhead.

1.8 Downsides of Rust

It's easy to talk about this language as if it is the panacea for all software engineering. For example

- "A high-level syntax with low-level performance!"
- "Concurrency without crashes!"
- "C with perfect safety!"

These slogans (sometimes overstated) are great. But for all of its merits, Rust does have some disadvantages.

1.8.1 Cvclic data structures

In Rust, it is difficult to model cyclic data like an arbitrary graph structure. Implementing a doubly-linked list is an undergraduate-level computer science problem. Yet Rust's safety checks do hamper progress here. If you're new to the language, avoid implementing these sorts of data structures until you're more familiar with Rust.

1.8.2 Compile times

Rust is slower at compiling code than its peer languages. It has a complex compiler toolchain that receives multiple intermediate representations and sends lots of code to the LLVM compiler. The unit of compilation for a Rust program is not an individual file but a whole package (known affectionately as a *crate*). As crates can include

multiple modules, these can be exceedingly large units to compile. Although this enables whole-of-crate optimization, it requires whole-of-crate compilation as well.

1.8.3 Strictness

It's impossible—well, difficult—to be lazy when programming with Rust. Programs won't compile until everything is just right. The compiler is strict, but helpful.

Over time, it's likely that you'll come to appreciate this feature. If you've ever programmed in a dynamic language, then you may have encountered the frustration of your program crashing because of a misnamed variable. Rust brings that frustration forward so that your users don't have to experience the frustration of things crashing.

1.8.4 Size of the language

Rust is large! It has a rich type system, several dozen keywords, and includes some features that are unavailable in other languages. These factors all combine to create a steep learning curve. To make this manageable, I encourage learning Rust gradually. Start with a minimal subset of the language and give yourself time to learn the details when you need these. That is the approach taken in this book. Advanced concepts are deferred until much later.

1.8.5 Hype

The Rust community is wary of growing too quickly and being consumed by hype. Yet, a number of software projects have encountered this question in their Inbox: "Have you considered rewriting this in Rust?" Unfortunately, software written in Rust is still software. It not immune to security problems and does not offer a panacea to all of software engineering's ills.

1.9 TLS security case studies

To demonstrate that Rust will not alleviate all errors, let's examine two serious exploits that threatened almost all internet-facing devices and consider whether Rust would have prevented those.

By 2015, as Rust gained prominence, implementations of SSL/TLS (namely, OpenSSL and Apple's own fork) were found to have serious security holes. Known informally as *Heartbleed* and *goto fail;*, both exploits provide opportunities to test Rust's claims of memory safety. Rust is likely to have helped in both cases, but it is still possible to write Rust code that suffers from similar issues.

1.9.1 Heartbleed

Heartbleed, officially designated as CVE-2014-0160, ¹⁶ was caused by re-using a buffer incorrectly. A *buffer* is a space set aside in memory for receiving input. Data can leak from one read to the next if the buffer's contents are not cleared between writes.

¹⁶ See "CVE-2014-0160 Detail," https://nvd.nist.gov/vuln/detail/CVE-2014-0160.

Why does this situation occur? Programmers hunt for performance. Buffers are reused to minimize how often memory applications ask for memory from the OS.

Imagine that we want to process some secret information from multiple users. We decide, for whatever reason, to reuse a single buffer through the course of the program. If we don't reset this buffer once we use it, information from earlier calls will leak to the latter ones. Here is a précis of a program that would encounter this error:

Rust does not protect you from logical errors. It ensures that your data is never able to be written in two places at the same time. It does not ensure that your program is free from all security issues.

1.9.2 Goto fail:

The goto fail; bug, officially designated as CVE-2014-1266,¹⁷ was caused by programmer error coupled with C design issues (and potentially by its compiler not pointing out the flaw). A function that was designed to verify a cryptographic key pair ended up skipping all checks. Here is a selected extract from the original SSLVerifySigned-ServerKeyExchange function with a fair amount of obfuscatory syntax retained:¹⁸

```
1 static OSStatus
 2 SSLVerifySignedServerKeyExchange(SSLContext *ctx,
                                     bool isRsa,
 4
                                     SSLBuffer signedParams,
 5
                                     uint8 t *signature,
 6
                                     UInt16 signatureLen)
 7 {
 8
     OSStatus
                      err:
                                     Initializes OSStatus with
 9
      . . .
                                     a pass value (e.g., 0)
10
      if ((err = SSLHashSHA1.update(
          &hashCtx, &serverRandom)) != 0)
12
                                                     A series of defensive
13
          goto fail;
                                                      programming checks
14
      if ((err = SSLHashSHA1.update(&hashCtx, &signedParams)) != 0)
```

¹⁷ See "CVE-2014-1266 Detail," https://nvd.nist.gov/vuln/detail/CVE-2014-1266.

¹⁸ Original available at http://mng.bz/RKGj.

```
Unconditional goto skips SSLHashSHAl.final()
      goto fail;
16
                                    and the (significant) call to sslRawVerify().
17
          goto fail;
18
      if ((err = SSLHashSHA1.final(&hashCtx, &hashOut)) != 0)
19
          goto fail;
20
     err = sslRawVerify(ctx,
21
22
                           ctx->peerPubKey,
23
                           dataToSign,
                                                    /* plaintext \*/
                                                   /* plaintext length \*/
24
                           dataToSignLen,
25
                           signature,
2.6
                           signatureLen);
       if(err) {
27
28
        sslErrorLog("SSLDecodeSignedServerKeyExchange: sslRawVerify "
29
                       "returned %d\n", (int)err);
30
          goto fail;
31
32
33 fail:
34
     SSLFreeBuffer(&signedHashes);
                                         Returns the pass value of 0, even for inputs
35
       SSLFreeBuffer(&hashCtx);
                                         that should have failed the verification test
36
      return err;
37 }
```

In the example code, the issue lies between lines 15 and 17. In C, logical tests do not require curly braces. C compilers interpret those three lines like this:

```
if ((err = SSLHashSHA1.update(&hashCtx, &signedParams)) != 0) {
   goto fail;
}
qoto fail;
```

Would Rust have helped? Probably. In this specific case, Rust's grammar would have caught the bug. It does not allow logical tests without curly braces. Rust also issues a warning when code is unreachable. But that doesn't mean the error is made impossible in Rust. Stressed programmers under tight deadlines make mistakes. In general, similar code would compile and run.

TIP Code with caution.

1.10 Where does Rust fit best?

Although it was designed as a systems programming language, Rust is a general-purpose language. It has been successfully deployed in many areas, which we discuss next.

1.10.1 Command-line utilities

Rust offers three main advantages for programmers creating command-line utilities: minimal startup time, low memory use, and easy deployment. Programs start their work quickly because Rust does not need to initialize an interpreter (Python, Ruby, etc.) or virtual machine (Java, C#, etc.).

As a bare metal language, Rust produces memory-efficient programs.¹⁹ As you'll see throughout the book, many types are zero-sized. That is, these only exist as hints to the compiler and take up no memory at all in the running program.

Utilities written in Rust are compiled as *static binaries* by default. This compilation method avoids depending on shared libraries that you must install before the program can run. Creating programs that can run without installation steps makes these easy to distribute.

1.10.2 Data processing

Rust excels at text processing and other forms of data wrangling. Programmers benefit from control over memory use and fast startup times. As of mid-2017, Rust touts the world's fastest regular expression engine. In 2019, the Apache Arrow data-processing project—foundational to the Python and R data science ecosystems—accepted the Rust-based DataFusion project.

Rust also underlies the implementation of multiple search engines, data-processing engines, and log-parsing systems. Its type system and memory control provide you with the ability to create high throughput data pipelines with a low and stable memory footprint. Small filter programs can be easily embedded into the larger framework via Apache Storm, Apache Kafka, or Apache Hadoop streaming.

1.10.3 Extending applications

Rust is well suited for extending programs written in a dynamic language. This enables JNI (Java Native Interface) extensions, C extensions, or Erlang/Elixir NIFs (native implemented functions) in Rust. C extensions are typically a scary proposition. These tend to be quite tightly integrated with the runtime. Make a mistake and you could be looking at runaway memory consumption due to a memory leak or a complete crash. Rust takes away a lot of this anxiety.

- Sentry, a company that processes application errors, finds that Rust is an excellent candidate for rewriting CPU-intensive components of their Python system.²⁰
- Dropbox used Rust to rewrite the file synchronization engine of its client-side application: "More than performance, [Rust's] ergonomics and focus on correctness have helped us tame sync's complexity."²¹

1.10.4 Resource-constrained environments

C has occupied the domain of microcontrollers for decades. Yet, the Internet of Things (IoT) is coming. That could mean many billions of insecure devices exposed to the network. Any input parsing code will be routinely probed for weaknesses. Given how infrequently firmware updates for these devices occur, it's critical that these are as

¹⁹ The joke goes that Rust is as close to bare metal as possible.

²⁰ See "Fixing Python Performance with Rust," http://mng.bz/ryxX.

²¹ See "Rewriting the heart of our sync engine," http://mng.bz/Vdv5.

secure as possible from the outset. Rust can play an important role here by adding a layer of safety without imposing runtime costs.

1.10.5 Server-side applications

Most applications written in Rust live on the server. These could be serving web traffic or supporting businesses running their operations. There is also a tier of services that sit between the OS and your application. Rust is used to write databases, monitoring systems, search appliances, and messaging systems. For example

- The npm package registry for the JavaScript and node.js communities is written in Rust.²²
- sled (https://github.com/spacejam/sled), an embedded database, can process a workload of 1 billion operations that includes 5% writes in less than a minute on a 16-core machine.
- Tantivy, a full text search engine, can index 8 GB of English Wikipedia in approximately 100 s on a 4-core desktop machine.²³

1.10.6 Desktop applications

There is nothing inherent in Rust's design that prevents it from being deployed to develop user-facing software. Servo, the web browser engine that acted as an incubator for Rust's early development, is a user-facing application. Naturally, so are games.

1.10.7 Desktop

There is still a significant need to write applications that live on people's computers. Desktop applications are often complex, difficult to engineer, and hard to support. With Rust's ergonomic approach to deployment and its rigor, it is likely to become the secret sauce for many applications. To start, these will be built by small, independent developers. As Rust matures, so will the ecosystem.

1.10.8 Mobile

Android, iOS, and other smartphone operating systems generally provide a blessed path for developers. In the case of Android, that path is Java. In the case of macOS, developers generally program in Swift. There is, however, another way.

Both platforms provide the ability for native applications to run on them. This is generally intended for applications written in C++, such as games, to be able to be deployed to people's phones. Rust is able to talk to the phone via the same interface with no additional runtime cost.

²² See "Community makes Rust an easy choice for npm: The npm Registry uses Rust for its CPU-bound bottle-necks," http://mng.bz/xm9B.

²³ See "Of tantivy's indexing," https://fulmicoton.com/posts/behold-tantivy-part2/.

1.10.9 Web

As you are probably aware, JavaScript is the language of the web. Over time though, this will change. Browser vendors are developing a standard called WebAssembly (Wasm) that promises to be a compiler target for many languages. Rust is one of the first. Porting a Rust project to the browser requires only two additional command-line commands. Several companies are exploring the use of Rust in the browser via Wasm, notably CloudFlare and Fastly.

1.10.10 Systems programming

In some sense, systems programming is Rust's raison d'être. Many large programs have been implemented in Rust, including compilers (Rust itself), video game engines, and operating systems. The Rust community includes writers of parser generators, databases, and file formats.

Rust has proven to be a productive environment for programmers who share Rust's goals. Three standout projects in this area include the following:

- Google is sponsoring the development of Fuchsia OS, an operating system for devices.²⁴
- Microsoft is actively exploring writing low-level components in Rust for Windows.²⁵
- Amazon Web Services (AWS) is building Bottlerocket, a bespoke OS for hosting containers in the cloud.²⁶

1.11 Rust's hidden feature: Its community

It takes more than software to grow a programming language. One of the things that the Rust team has done extraordinarily well is to foster a positive and welcoming community around the language. Everywhere you go within the Rust world, you'll find that you'll be treated with courtesy and respect.

1.12 Rust phrase book

When you interact with members of the Rust community, you'll soon encounter a few terms that have special meaning. Understanding the following terms makes it easier to understand why Rust has evolved the way that it has and the problems that it attempts to solve:

 Empowering everyone—All programmers regardless of ability or background are welcome to participate. Programming, and particularly systems programming, should not be restricted to a blessed few.

²⁴ See "Welcome to Fuchsia!," https://fuchsia.dev/.

²⁵ See "Using Rust in Windows," http://mng.bz/A0vW.

²⁶ See "Bottlerocket: Linux-based operating system purpose-built to run containers," https://aws.amazon.com/bottlerocket/.

Summary 27

Blazingly fast—Rust is a fast programming language. You'll be able to write programs that match or exceed the performance of its peer languages, but you will have more safety guarantees.

- Fearless concurrency—Concurrent and parallel programming have always been seen as difficult. Rust frees you from whole classes of errors that have plagued its peer languages.
- No Rust 2.0—Rust code written today will always compile with a future Rust compiler. Rust is intended to be a reliable programming language that can be depended upon for decades to come. In accordance with semantic versioning, Rust is never backward-incompatible, so it will never release a new major version.
- Zero-cost abstractions—The features you gain from Rust impose no runtime cost.
 When you program in Rust, safety does not sacrifice speed.

Summary

- Many companies have successfully built large software projects in Rust.
- Software written in Rust can be compiled for the PC, the browser, and the server, as well as mobile and IoT devices.
- The Rust language is well loved by software developers. It has repeatedly won Stack Overflow's "most loved programming language" title.
- Rust allows you to experiment without fear. It provides correctness guarantees
 that other tools are unable to provide without imposing runtime costs.
- With Rust, there are three main command_line tools to learn:
 - cargo, which manages a whole crate
 - rustup, which manages Rust installations
 - rustc, which manages compilation of Rust source code
- Rust projects are not immune from all bugs.
- Rust code is stable, fast, and light on resources.

Part 1

Rust language distinctives

Part 1 of the book is a quick-fire introduction to the Rust programming language. By the end of the chapters in this part, you will have a good understanding of Rust syntax and know what motivates people to choose Rust. You will also understand some fundamental differences between Rust and its peer languages.

Language foundations

This chapter covers

- Coming to grips with the Rust syntax
- Learning fundamental types and data structures
- Building command-line utilities
- Compiling programs

This chapter introduces you to the fundamentals of Rust programming. By the end of the chapter, you will be able to create command-line utilities and should be able to get the gist of most Rust programs. We'll work through most of the language's syntax, but defer much of the detail about *why* things are *how* they are for later in the book.

NOTE Programmers who have experience with another programming language will benefit the most from this chapter. If you are an experienced Rust programmer, feel free to skim through it.

Beginners are welcomed. Rust's community strives to be responsive to newcomers. At times, you may strike a mental pothole when you encounter terms such as *lifetime elision, hygienic macros, move semantics*, and *algebraic data types* without context. Don't

be afraid to ask for help. The community is much more welcoming than these helpful, yet opaque, terms might suggest.

In this chapter, we will build grep-lite, a greatly stripped-down version of the ubiquitous grep utility. Our grep-lite program looks for patterns within text and prints lines that match. This simple program allows us to focus on the unique features of Rust.

The chapter takes a spiral approach to learning. A few concepts will be discussed multiple times. With each iteration, you will find yourself learning more. Figure 2.1 shows a completely unscientific map of the chapter.

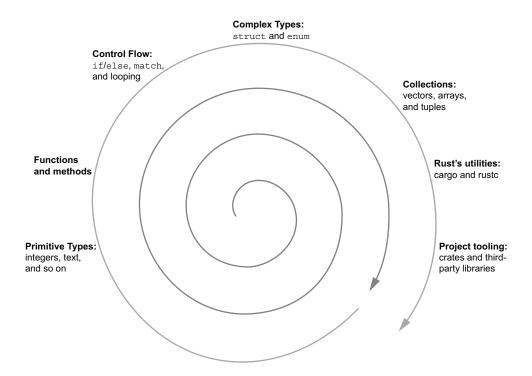

Figure 2.1 Chapter topic outline. Starting with primitive types, the chapter progresses through several concepts with increasing levels of depth.

It's highly recommended that you follow along with the examples in this book. As a reminder, to access or download the source code for the listings, use either of these two sources:

- https://manning.com/books/rust-in-action
- https://github.com/rust-in-action/code

2.1 Creating a running program

Every plain text file has a hidden superpower: when it includes the right symbols, it can be converted into something that can be interpreted by a CPU. That is the magic of a programming language. This chapter's aim is to allow you to become familiar with the process of converting Rust source code into a running program.

Understanding this process is more fun than it sounds! And it sets you up for an exciting learning journey. By the end of chapter 4, you will have implemented a virtual CPU that can also interpret programs that you create.

2.1.1 Compiling single files with rustc

Listing 2.1 is a short, yet complete Rust program. To translate it into a working program, we use software called a *compiler*. The compiler's role is to translate the source code into machine code, as well as take care of lots of bookkeeping to satisfy the operating system (OS) and CPU that it is a runnable program. The Rust compiler is called *rustc*. You'll find the source code for listing 2.1 in the file ch2/ok.rs.

Listing 2.1 Almost the shortest valid Rust program

```
1 fn main() {
2  println!("OK")
3 }
```

To compile a single file written in Rust into a working program

- 1 Save your source code to a file. In our case, we'll use the filename ok.rs.
- 2 Make sure that the source code includes a main() function.
- 3 Open a shell window such as Terminal, cmd.exe, Powershell, bash, zsh, or any other.
- 4 Execute the command rustc <file>, where <file> is the file you want to compile.

When compilation succeeds, rustc sends no output to the console. Behind the scenes, rustc has dutifully created an executable, using the input filename to choose the output filename.

Assuming that you've saved listing 2.1 to a file called ok.rs, let's see what that looks like. The following snippet provides a short demonstration of the process:

```
$ rustc ok.rs
$ ./ok
OK

For Windows, include the .exe filename extension (for example, ok.exe).
```

2.1.2 Compiling Rust projects with cargo

Most Rust projects are larger than a single file. These typically include dependencies. To prepare ourselves for that, we'll use a higher-level tool than rustc, called cargo. cargo understands how to drive rustc (and much more).

Migrating from a single file workflow managed by rustc to one managed by cargo is a two-stage process. The first is to move that original file into an empty directory. Then execute the cargo init command.

Here is a detailed overview of that process, assuming that you are starting from a file called ok.rs generated by following the steps in the previous section:

- 1 Run mkdir roject> to create an empty directory (e.g., mkdir ok).
- 2 Move your source code into the directory (e.g., mv ok.rs ok).
- 3 Change to the ct> directory (e.g., cd ok).
- 4 Run cargo init.

From this point on, you can issue cargo run to execute your project's source code. One difference from rustc is that compiled executables are found in a cproject>/ target subdirectory. Another is that cargo provides much more output by default:

```
$ cargo run
    Finished dev [unoptimized + debuginfo] target(s) in 0.03s
    Running `target/debug/ok`
OK
```

If you're ever curious about what cargo is doing under the hood to drive rustc, add the verbose flag (-v) to your command:

```
$ rm -rf target/
                                     Added here to provoke
$ cargo run -v
                                     cargo into compiling
  Compiling ok v0.1.0 (/tmp/ok)
                                     the project from
    Running `rustc
                                     scratch
     --crate-name ok
     --edition=2018
    ok.rs
     --error-format=json
     --json=diagnostic-rendered-ansi
     --crate-type bin
     --emit=dep-info,link
     -C embed-bitcode=no
     -C debuginfo=2
     -C metadata=55485250d3e77978
     -C extra-filename=-55485250d3e77978
     --out-dir /tmp/ok/target/debug/deps
     -C incremental=/tmp/target/debug/incremental
     -L dependency=/tmp/ok/target/debug/deps
     -C link-arg=-fuse-ld=lld`
    Finished dev [unoptimized + debuginfo] target(s) in 0.31s
    Running `target/debug/ok`
```

2.2 A glance at Rust's syntax

Rust is boring and predictable where possible. It has variables, numbers, functions, and other familiar things that you have seen in other languages. For example, it delimits blocks with curly brackets ({ and }), it uses a single equals sign as its assignment operator (=), and it is whitespace-agnostic.

2.2.1 Defining variables and calling functions

Let's look at another short listing to introduce some fundamentals: defining variables with type annotations and calling functions. Listing 2.2 prints (a + b) + (c + d) = 90 to the console. As you can see from lines 2–5 in the listing, there are multiple syntactic choices for annotating data types to integers. Use whichever feels most natural for the situation at hand. The source code for this listing is in ch2/ch2-first-steps.rs.

Listing 2.2 Adding integers using variables and declaring types

```
Rust is flexible with
                                 Types can be inferred
     the location of the
                                 by the compiler...
       main() function.
                                    ...or declared by the programmer
 1 fn main() { <-
                                    when creating variables.
   let a = 10;
                                      Numeric types can include a type
     let b: i32 = 20;
 3
                                      annotation in their literal form.
     let c = 30i32;
     let d = 30_i32;
 5
                                                              Numbers can include underscores,
     let e = add(add(a, b), add(c, d));
                                                              which are intended to increase
 7
                                                              readability and have no functional
     println!("(a + b) + (c + d) = \{\}", e);
9 }
10
                                                     Type declarations are required
11 fn add(i: i32, j: i32) -> i32 {
                                                     when defining functions.
                       Functions return the last
13 }
                       expression's result so that
                       return is not required.
```

NOTE In the listing, be careful about adding a semicolon to the add() function declaration. This changes the semantics, returning () (unit) rather than i32.

Although there are only 13 lines of code, there is quite a lot packed into listing 2.2. Here's a brief description that should provide the gist of what's going on. We will cover the details in the rest of the chapter.

In line 1 (fn main() {), the fn keyword begins a function definition. The entry point to all Rust programs is main(). It takes no arguments and returns no value. Code blocks, also known as *lexical scopes*, are defined with curly braces: { and }.

In line 2 (let a = 10;), we use let to declare *variable bindings*. Variables are *immutable* by default, meaning that they are read-only rather than read-write. And finally, statements are delimited with semicolons (;).

In line 3 (let b: i32 = 20;), you can designate a specific data type for the compiler. At times, this will be required as the compiler will be unable to deduce a unique type on your behalf.

In line 4 (let c = 30i32;), you'll note that Rust's numeric literals can include types annotations. This can be helpful when navigating complex numerical expressions. And

¹ This isn't technically correct, but is accurate enough for now. If you're an experienced Rust programmer skimming through this chapter, you'll know that main() returns() (unit) by default and can also return a Result.

in line 5 (let $c = 30_i32_i$), you'll see that Rust permits the use of underscores within numeric literals. These increase readability but are insignificant to the compiler. In line 6 (let $e = add(add(a, b), add(c, d))_i$), it should be easy to see that calling functions looks like what you've experienced in most other programming languages.

In line 8 (println!("(a + b) + (c + d) = {}", e);), println!() is a *macro*, which is function-like but returns code rather than values. When printing to the console, every input data type has its own way of being represented as a text string. println!() takes care of figuring out the exact methods to call on its arguments.

Strings use double quotes (") rather than single quotes ('). Rust uses single quotes for single characters, which are a distinct type, char. And with Rust, string formatting uses {} as a placeholder, rather than the C-like printf style of \$s or other variants.

Finally, in line 10 (fn add(...) -> i32 {), you can see that Rust's syntax for defining functions is similar to those programming languages that use explicit type declarations. Commas delimit parameters, and type declarations follow variable names. The dagger (->) or thin arrow syntax indicates the return type.

2.3 Numbers

Computers have been associated with numbers for longer than you have been able to say "formula translator." This section discusses how to create numeric types in Rust and how to perform operations on these.

2.3.1 Integers and decimal (floating-point) numbers

Rust uses a relatively conventional syntax for creating integers (1, 2, ...) and floating-point numbers (1.0, 1.1, ...). Operations on numbers use *infix notation*, meaning that numeric expressions look like those that you're used to seeing in most programming languages. To operate on multiple types, Rust also allows the same token (+) for addition. This is called *operator overloading*. Some notable differences from other languages follow:

- Rust includes a large number of numeric types. You will become used to declaring the size in bytes, which affects how many numbers the type can represent and whether your type is able to represent negative numbers.
- Conversions between types are always explicit. Rust does not automatically convert your 16-bit integer into a 32-bit integer.
- Rust's numbers can have methods. For example, to round 24.5 to the nearest integer, Rust programmers use 24.5_f32.round() rather than (round(24.5_f32)). Here, the type suffix is required because a concrete type is necessary.

To start, let's consider a small example. You'll find the code in ch2/ch2-intro-to-numbers.rs in the examples for this book. Listing 2.3 prints these few lines to the console:

```
20 + 21 + 22 = 63
1000000000000
```

Numbers 37

Listing 2.3 Numeric literals and basic operations on numbers in Rust

```
Rust infers a type
                                                                             ...which is done
                                                     on your behalf if you
                                                                             by adding type
                  1 fn main() {
                                                  don't supply one...
                                                                            annotations
                  2
                       let twenty = 20;
                                                                            (i32)...
                  3
                       let twenty one: i32 = 21;
                      let twenty two = 22i32;
                  4
                                                                ...or type suffixes.
                  5
                       let addition = twenty + twenty one + twenty two;
                  6
                       println!("{} + {} + {} = {} ", twenty, twenty_one, twenty_two, addition);
 Numbers
                  8
                                                                        Underscores increase readability and are ignored by the compiler.
     have
                      let one million: i64 = 1 000 000;
                  9
 methods.
                10
                      println!("{}", one million.pow(2));
                 11
                                                      Creates an array of numbers, which must all be the
  Floating-
                 12 let forty twos = [
                                                     same type, by surrounding those with square brackets

                18/
     ...and
                19 }
                                            Elements within arrays can be
   optional
                                        indexed numerically, starting at 0.
underscores.
```

2.3.2 Integers with base 2, base 8, and base 16 notation

Rust also has built-in support for numeric literals that allow you to define integers in base 2 (binary), base 8 (octal), and base 16 (hexadecimal). This notation is also available within the formatting macros like println!. Listing 2.4 demonstrates the three styles. You can find the source code for this listing in ch2/ch2-non-base2.rs. It produces the following output:

```
base 10: 3 30 300
base 2: 11 11110 100101100
base 8: 3 36 454
base 16: 3 1e 12c
```

Listing 2.4 Using base 2, base 8, and base 16 numeric literals

```
The 0b prefix indicates
  1 fn main() {
                                  binary (base 2) numerals.
      let three = 0b11;
      let thirty = 0036;
  3
                                           The Oo prefix indicates
      let three hundred = 0x12C;
  4
                                           octal (base 8) numerals.
  5
      println!("base 10: {} {} {}", three, thirty, three hundred);
      println!("base 2: {:b} {:b}", three, thirty, three hundred);
     println!("base 8: {:o} {:o}", three, thirty, three hundred);
      println!("base 16: {:x} {:x} {:x}", three, thirty, three hundred);
  9
 10 }
The 0x prefix indicates
hexadecimal (base 16) numerals.
```

In binary (base 2) numerals, 0b11 equals 3 because $3 = 2 \times 1 + 1 \times 1$. With octal (base 8) numerals, 0o36 equals 30 because $30 = 8 \times 3 + 1 \times 6$. And with hexadecimal (base 16) numerals, 0x12C equals 300 because $300 = 256 \times 1 + 16 \times 2 + 1 \times 12$. Table 2.1 shows the types that represent scalar numbers.

Table 2.1 Rust types for representing scalar (single) numbers

i8, i16, i32, i64	Signed integers ranging from 8 bit to 64 bit.
u8, u16, u32, u64	Unsigned integers ranging from 8 bit to 64 bit.
f32, f64	Floating-point numbers in 32-bit and 64-bit variants.
isize, usize	Integers that assume the CPU's "native" width. For example, in 64-bit CPUs, usize and isize will be 64-bits wide.

Rust contains a full complement of numeric types. The types are grouped into a few families:

- Signed integers (i) represent negative as well as positive integers.
- Unsigned integers (u) only represent positive integers but can go twice as high as their signed counterparts.
- Floating-point types (f) represent real numbers with special bit patterns to represent infinity, negative infinity, and "not a number" values.

Integer width is the number of bits that the type uses in RAM and in the CPU. Types that take up more space, such as u32 vs. i8, can represent a wider range of numbers. But this incurs the expense of needing to store extra zeros for smaller numbers, as table 2.2 shows.

Table 2.2 Multiple bit patterns can represent the same number.

Number	Туре	Bit pattern in memory
20	u32	000000000000000000000000000000000000000
20	i8	00010100
20	f32	010000011010000000000000000000000

Although we've only touched on numbers, we nearly have enough exposure to Rust to create a prototype of our pattern-matching program. But let's look at comparing numbers before we create our program.

2.3.3 Comparing numbers

Rust's numeric types support a large suite of comparisons that you're probably familiar with. Enabling support for these comparisons is provided by a feature that you have not encountered yet. It is called *traits*.² Table 2.3 summarizes the comparison operators available to you.

² For the curious and eager, the traits involved here are std::cmp::PartialOrd and std::cmp::PartialEq.

Numbers 39

Table 2.3	Mathematical	operators	supported b	v Rust's	numeric types
-----------	--------------	-----------	-------------	----------	---------------

Operator	Rust syntax	Example
Less than (<)	<	1.0 < 2.0
Greater than (>)	>	2.0 > 1.0
Equal to (=)	==	1.0 == 1.0
Unequal to (≠)	!=	1.0 != 2.0
Equal to or less than (≤)	<=	1.0 <= 2.0
Equal to greater than or (\geq)	>=	2.0 >= 1.0

That support does include a few caveats. We'll look at these conditions in the rest of this section.

IMPOSSIBLE TO COMPARE DIFFERENT TYPES

Rust's type safety requirements prevent comparisons between types. For example, this code does not compile:

```
fn main() {
  let a: i32 = 10;
  let b: u16 = 100;

  if a < b {
    println!("Ten is less than one hundred.");
  }
}</pre>
```

To appease the compiler, we need to use an as operator to cast one of the operands to the other's type. The following code shows this type cast: b as i32:

```
fn main() {
  let a: i32 = 10;
  let b: u16 = 100;

  if a < (b as i32) {
    println!("Ten is less than one hundred.");
  }
}</pre>
```

It is safest to cast the smaller type to a larger one (for example, a 16-bit type to a 32-bit type). This is sometimes referred to as *promotion*. In this case, we could have demoted a down to a u16, but such a move is generally more risky.

WARNING Using type casts carelessly will cause your program to behave unexpectedly. For example, the expression 300_i32 as i8 returns 44.

In some cases, using the as keyword is too restrictive. It's possible to regain fuller control over the type conversion process at the cost of introducing some bureaucracy. The

following listing shows a Rust method to use instead of the as keyword when the conversion might fail.

Listing 2.5 The try into() method converts between types

```
1 use std::convert::TryInto;
                                           Enables try into() to be
                                           called on those types that have
 3 fn main() {
                                           implemented it (such as u16)
    let a: i32 = 10;
    let b: u16 = 100;
                                      try_into() returns a Result
                                      type that provides access to
 7
     let b = b.try into()
                                      the conversion attempt.
               .unwrap();
 9
10 if a < b {
     println!("Ten is less than one hundred.");
11
12 }
13 }
```

Listing 2.5 introduces two new Rust concepts: traits and error handling. On line 1, the use keyword brings the std::convert::TryInto trait into local scope. This unlocks the try_into() method of the b variable. We'll bypass a full explanation of why this occurs for now. In the meantime, consider a *trait* as a collection of methods. If you are from an object-oriented background, traits can be thought of as *abstract classes* or *interfaces*. If your programming experience is in functional languages, you can think of traits as *type classes*.

Line 7 provides a glimpse of error handling in Rust. b.try_into() returns an i32 value wrapped within a Result. Result is introduced properly in chapter 3. It can contain either a success value or an error value. The unwrap() method can handle the success value and returns the value of b as an i32 here. If the conversion between u16 and i32 were to fail, then calling unsafe() would crash the program. As the book progresses, you will learn safer ways of dealing with Result rather than risking the program's stability!

A distinguishing characteristic of Rust is that it only allows a type's methods to be called when the trait is within local scope. An implicit prelude enables common operations such as addition and assignment to be used without explicit imports.

TIP To understand what is included in local scope by default, you should investigate the std::prelude module. Its documentation is available online at https://doc.rust-lang.org/std/prelude/index.html.

Floating-point hazards

Floating-point types (f32 and f64, for example) can cause serious errors for the unwary. There are (at least) two reasons for this:

 These often approximate the numbers that they're representing. Floating-point types are implemented in base 2, but we often want to calculate numbers in Numbers 41

base 10. This mismatch creates ambiguity. Moreover, although often described as representing the real numbers, floating point values have a limited precision. Representing all of the reals would require infinite precision.

■ These can represent values that have unintuitive semantics. Unlike integers, floating-point types have some values that do not play well together (by design). Formally, these only have a partial equivalence relation. This is encoded in Rust's type system. f32 and f64 types only implement the std::cmp::PartialEq trait, whereas other numeric types also implement std::cmp::Eq.

To prevent these hazards, here are two guidelines to follow:

- Avoid testing floating-point numbers for equality.
- Be wary when results may be mathematically undefined.

Using equality to compare floating-point numbers can be highly problematic. Floating-point numbers are implemented by computing systems that use binary (base 2) mathematics, but are often asked to perform operations on decimal (base 10) numbers. This poses a problem because many values we care about, such as 0.1, have no exact representation in binary.^a

To illustrate the problem, consider the following snippet. Should it run successfully, or should it crash? Although the expression that is being evaluated (0.1 + 0.2 = 0.3) is a mathematical tautology, it crashes on most systems that run it:

```
fn main() {
  assert! (0.1 + 0.2 == 0.3);
}
assert! crashes the program
unless its argument evaluates
to true.
```

But not all. It turns out that the data type can affect whether the program succeeds or fails. The following code, available at ch2/ch2-add-floats.rs, interrogates the internal bit patterns of each value to find where the differences lie. It then performs the test in the previous example against both f32 and f64 types. Only one test passes:

```
1 fn main() {
2 let abc: (f32, f32, f32) = (0.1, 0.2, 0.3);
    let xyz: (f64, f64, f64) = (0.1, 0.2, 0.3);
4
5 println!("abc (f32)");
    println!(" 0.1 + 0.2: {:x}", (abc.0 + abc.1).to bits());
6
    println!(" 0.3: {:x}", (abc.2).to_bits());
7
    println!();
8
9
    println!("xyz (f64)");
10
11
    println!(" 0.1 + 0.2: {:x}", (xyz.0 + xyz.1).to_bits());
12
    println!(" 0.3: {:x}", (xyz.2).to bits());
13
    println!();
14
    assert!(abc.0 + abc.1 == abc.2); Runs successfully
15
    16
17 }
```

(continued)

When executed, the program successfully generates the short report that follows, which reveals the error. After that, it crashes. Significantly, it crashes on line 14, when it compares the result of the £64 values:

```
abc (f32)
    0.1 + 0.2: 3e99999a
        0.3: 3e99999a

xyz (f64)
    0.1 + 0.2: 3fd333333333334
        0.3: 3fd333333333333

thread 'main' panicked at 'assertion failed: xyz.0 + xyz.1 == xyz.2',
    ch2-add-floats.rs.rs:14:5
note: run with `RUST_BACKTRACE=1` environment variable to display
    a backtrace
```

Generally speaking, it is safer to test whether mathematical operations fall within an acceptable margin of their true mathematical result. This margin is often referred to as the *epsilon*.

Rust includes some tolerances to allow comparisons between floating-point values. These tolerances are defined as f32::EPSILON and f64::EPSILON. To be more precise, it's possible to get closer to how Rust is behaving under the hood, as the following small example shows:

```
fn main() {
  let result: f32 = 0.1 + 0.1;
  let desired: f32 = 0.2;
  let absolute_difference = (desired - result).abs();
  assert!(absolute_difference <= f32::EPSILON);
}</pre>
```

In the example, what actually happens is interesting, but mostly irrelevant. The Rust compiler actually delegates the comparison to the CPU. Floating-point operations are implemented using bespoke hardware within the chip.^b

Operations that produce mathematically undefined results, such as taking the square root of a negative number ($-42.0.\mathrm{sqrt}()$), present particular problems. Floating-point types include "not a number" values (represented in Rust syntax as NAN values) to handle these cases.

NAN values poison other numbers. Almost all operations interacting with NAN return NAN. Another thing to be mindful of is that, by definition, NAN values are never equal. This small program will always crash:

```
fn main() {
  let x = (-42.0_f32).sqrt();
  assert_eq!(x, x);
}
```

Numbers 43

To program defensively, make use of the $is_nan()$ and $is_finite()$ methods. Inducing a crash, rather than silently proceeding with a mathematical error, allows you to debug close to what has caused the problem. The following illustrates using the $is_finite()$ method to bring about this condition:

```
fn main() {
  let x: f32 = 1.0 / 0.0;
  assert!(x.is_finite());
}
```

- ^a If this is confusing to think about, consider that many values, such as 1/3 (one third), have no exact representation within the decimal number system.
- ^b Illegal or undefined operations trigger a CPU exception. You will read about those in chapter 12.

2.3.4 Rational, complex numbers, and other numeric types

Rust's standard library is comparatively slim. It excludes numeric types that are often available within other languages. These include

- Many mathematical objects for working with rational numbers and complex numbers
- Arbitrary size integers and arbitrary precision floating-point numbers for working with very large or very small numbers
- Fixed-point decimal numbers for working with currencies

To access these specialized numeric types, you can use the num crate. *Crates* are Rust's name for packages. Open source crates are shared at the https://crates.io repository, which is where cargo downloads num from.

Listing 2.6 demonstrates adding two complex numbers together. If you're unfamiliar with the term *complex numbers*, these are two-dimensional, whereas numbers that you deal with day to day are one-dimensional. Complex numbers have "real" and "imaginary" parts and are denoted as $\ensuremath{<}$ + $\ensuremath{<}$ imaginary>i. For example, 2.1 + -1.2i is a single complex number. That's enough mathematics. Let's look at the code.

Here is the recommended workflow to compile and run listing 2.6:

1 Execute the following commands in a terminal:

```
git clone --depth=1 https://github.com/rust-in-action/code rust-in-action
cd rust-in-action/ch2/ch2-complex
cargo run
```

- 2 For those readers who prefer to learn by doing everything by hand, the following instructions will achieve the same end result:
 - a Execute the following commands in a terminal:

```
cargo new ch2-complex
cd ch2-complex
```

³ Mechanical engineers use *j* rather than *i*.

b Add version 0.4 of the num crate into the [dependencies] section of Cargo.toml. That section will look like this:

```
[dependencies]
num = "0.4"
```

- Replace src/main.rs with the source code from listing 2.6 (available at ch2/ch2-complex/src/main.rs).
- d Execute cargo run.

After several lines of intermediate output, cargo run should produce the following output:

13.2 + 21.02i

Listing 2.6 Calculating values with complex numbers

```
1 use num::complex::Complex;
2
3 fn main() {
4  let a = Complex { re: 2.1, im: -1.2 };
5  let b = Complex::new(11.1, 22.2);
6  let result = a + b;
7
8  println!("{} + {}i", result.re, result.im)
9 }
Accesses fields with the dot operator
The use keyword brings the Complex type into local scope.

Every Rust type has a literal syntax.

Most types implement a new() static method.
9 }
```

Some points from the listing are worth pausing to consider:

- The use keyword pulls crates into local scope, and the namespace operator (::) restricts what's imported. In our case, only a single type is required: Complex.
- Rust does not have constructors; instead, every type has a literal form. You can initialize types by using the type name (Complex) and assigning their fields (re, im) values (such as 2.1 or -1.2) within curly braces ({ }).
- *Many types implement a* new() *method for simplicity*. This convention, however, is not part of the Rust language.
- To access fields, Rust programmers use the dot operator (.). For example, the num:: complex::Complex type has two fields: re represents the real part, and im represents the imaginary part. Both are accessible with the dot operator.

Listing 2.6 also introduces some new commands. It demonstrates two forms of initializing non-primitive data types.

One is a *literal* syntax available as part of the Rust language (line 4). The other is the new() static method, which is implemented by convention only and isn't defined as part of the language (line 5). A *static method* is a function that's available for a type, but it's not an instance of that type.⁴

⁴ Although Rust is not object-oriented (it's impossible to create a subclass, for example), Rust makes use of some terminology from that domain. It's common to hear of Rust programmers discussing instances, methods, and objects.

Flow control 45

The second form is often preferred in real-world code because library authors use a type's new() method to set defaults. It also involves less clutter.

Shortcut for adding a third-party dependency to a project

Adding num v0.4.0 to dependencies

I recommend that you install the cargo-edit crate to enable the cargo add subcommand. You can do this with the following code:

```
$ cargo install cargo-edit
    Updating crates.io index
Installing cargo-edit v0.6.0
...
Installed package `cargo-edit v0.6.0` (executables `cargo-add`,
    `cargo-rm`, `cargo-upgrade`)

Up to this point, we have manually added dependencies to Cargo.toml. The cargo add command simplifies this process by editing the file correctly on your behalf:

$ cargo add num
    Updating 'https://github.com/rust-lang/crates.io-index' index
```

We've now addressed how to access built-in numeric types and types available from third-party libraries. We'll move on to discussing some more of Rust's features.

2.4 Flow control

Programs execute from top to bottom, except when you don't want that. Rust has a useful set of *flow control* mechanisms to facilitate this. This section provides a brief tour of the fundamentals.

2.4.1 For: The central pillar of iteration

The for loop is the workhorse of iteration in Rust. Iterating through collections of things, including iterating over collections that may have infinitely many values, is easy. The basic form is

```
for item in container {
   // ...
}
```

This basic form makes each successive element in container available as item. In this way, Rust emulates many dynamic languages with an easy-to-use, high-level syntax. However, it does have some pitfalls.

Counterintuitively, once the block ends, accessing the container another time becomes invalid. Even though the container variable remains within local scope, its *lifetime* has ended. For reasons that are explained in chapter 4, Rust assumes that container is no longer needed once the block finishes.

When you want to reuse container later in your program, use a reference. Again, for reasons that are explained in chapter 4, when a reference is omitted, Rust assumes that container is no longer needed. To add a reference to the container, prefix it with an ampersand (&) as this example shows:

```
for item in &container {
   // ...
}
```

If you need to modify each item during the loop, you can use a *mutable reference* by including the mut keyword:

```
for item in &mut collection {
   // ...
}
```

As an implementation detail, Rust's for loop construct is expanded to method calls by the compiler. As the following table shows, these three forms of for each map to a different method.

Shorthand	Equivalent to	Access
for item in collection	for item in IntoIterator::into_iter(collection)	Ownership
for item in &collection	for item in collection.iter()	Read-only
for item in &mut collection	for item in collection.iter_mut()	Read-write

ANONYMOUS LOOPS

When a local variable is not used within a block, by convention, you'll use an underscore (_). Using this pattern in conjunction with the _exclusive range syntax_ (n..m) and the inclusive range syntax (n..=m) makes it clear that the intent is to perform a loop for a fixed number of times. Here's an example:

```
for _ in 0..10 {
    // ...
}
```

AVOID MANAGING AN INDEX VARIABLE

In many programming languages, it's common to loop through things by using a temporary variable that's incremented at the end of each iteration. Conventionally, this variable is named i (for index). A Rust version of that pattern is

```
let collection = [1, 2, 3, 4, 5];
for i in 0..collection.len() {
  let item = collection[i];
  // ...
}
```

Flow control 47

This is legal Rust. It's also essential in cases when iterating directly over collection via for item in collection is impossible. However, it is generally discouraged. The manual approach introduces two problems with this:

- Performance—Indexing values with the collection[index] syntax incurs runtime costs for bounds checking. That is, Rust checks that index currently exists within collection as valid data. Those checks are not necessary when iterating directly over collection. The compiler can use compile-time analysis to prove that illegal access is impossible.
- *Safety*—Periodically accessing collection over time introduces the possibility that it has changed. Using a for loop over collection directly allows Rust to guarantee that the collection remains untouched by other parts of the program.

2.4.2 Continue: Skipping the rest of the current iteration

The continue keyword operates as you would expect. Here's an example:

```
for n in 0..10 {
  if n % 2 == 0 {
    continue;
  }
  // ...
}
```

2.4.3 While: Looping until a condition changes its state

The while loop proceeds as long as a condition holds. The condition, formally known as a *predicate*, can be any expression that evaluates to true or false. This (non-functioning) snippet takes air quality samples, checking to avoid anomalies:

```
let mut samples = vec![];
while samples.len() < 10 {
  let sample = take_sample();
  if is_outlier(sample) {
    continue;
  }
  samples.push(sample);
}</pre>
```

USING WHILE TO STOP ITERATING ONCE A DURATION IS REACHED

Listing 2.7 (source code available at ch2/ch2-while-true-incr-count.rs) provides a working example of while. It isn't an ideal method for implementing benchmarks, but can be a useful tool to have in your toolbox. In the listing, while continues to execute a block when a time limit is not reached.

Listing 2.7 Testing how fast your computer can increment a counter

```
1 use std::time::{Duration, Instant};
                                                    This form of an import hasn't been seen
                                                    before. It brings the Duration and Instant
 3 fn main() {
                                                    types from std::time into local scope.
    let mut count = 0;
 5
     let time limit = Duration::new(1,0);
                                                                   Creates a Duration that
     let start = Instant::now();
                                                                   represents 1 second
 7
    while (Instant::now() - start) < time_limit { <-</pre>
                                                                  Accesses time from
 9
          count += 1;
                                                                 the system's clock
                                    An Instant minus an Instant
10
                                      returns a Duration.
11
      println!("{}", count);
12 }
```

AVOID WHILE WHEN ENDLESSLY LOOPING

Most Rust programmers avoid the following idiom to express looping forever. The preferred alternative is to use the loop keyword, explained in the next section.

```
while true {
  println!("Are we there yet?");
}
```

2.4.4 Loop: The basis for Rust's looping constructs

Rust contains a loop keyword for providing more control than for and while. loop executes a code block again and again, never stopping for a tea (or coffee) break. loop continues to execute until a break keyword is encountered or the program is terminated from the outside. Here's an example showing the loop syntax:

```
loop {
   // ...
}
```

loop is often seen when implementing long-running servers, as the following example shows:

```
loop {
  let requester, request = accept_request();
  let result = process_request(request);
  send_response(requester, result);
}
```

2.4.5 Break: Aborting a loop

The break keyword breaks out of a loop. In this regard, Rust's generally operates as you are used to:

```
for (x, y) in (0..).zip(0..) {
  if x + y > 100 {
    break;
}
```

Flow control 49

```
// ...
}
```

BREAK FROM NESTED LOOPS

You can break out of a nested loop with loop labels.⁵ A *loop label* is an identifier prefixed with an apostrophe ('), like this example shows:

```
'outer: for x in 0.. {
  for y in 0.. {
    for z in 0.. {
      if x + y + z > 1000 {
        break 'outer;
      }
      // ...
  }
}
```

Rust does not include the goto keyword, which provides the ability to jump to other parts of the program. The goto keyword can make control flow confusing, and its use is generally discouraged. One place where it is still commonly used, though, is to jump to and clean up a section of a function when an error condition is detected. Use loop labels to enable that pattern.

2.4.6 If, if else, and else: Conditional branching

So far, we've indulged in the exciting pursuit of looking for numbers within lists of numbers. Our tests have involved utilizing the if keyword. Here's an example:

```
if item == 42 {
   // ...
}
```

if accepts any expression that evaluates to a Boolean value (e.g., true or false). When you want to test multiple expressions, it's possible to add a chain of if else blocks. The else block matches anything that has not already been matched. For example

```
if item == 42 {
   // ...
} else if item == 132 {
   // ...
} else {
   // ...
}
```

⁵ This functionality is also available with continue, but it's less common.

Rust has no concept of "truthy" or "falsey" types. Other languages allow special values such as 0 or an empty string to stand in for false and for other values to represent true, but Rust doesn't allow this. The only value that can be used for true is true, and for false, use false.

Rust is an expression-based language

In programming languages from this heritage, all expressions return values and almost everything is an expression. This heritage reveals itself through some constructs that are not legal in other languages. In idiomatic Rust, the return keyword is omitted from functions as shown in the following snippet:

```
fn is_even(n: i32) -> bool {
  n % 2 == 0
}
```

For example, Rust programmers assign variables from conditional expressions:

```
fn main() {
  let n = 123456;
  let description = if is_even(n) {
    "even"
  } else {
    "odd"
  };
  println!("{} is {}", n, description);
}
Prints "123456
is even"
}
```

This can be extended to other blocks including match like this:

```
fn main() {
  let n = 654321;
  let description = match is_even(n) {
    true => "even",
    false => "odd",
  };
  println!("{} is {}", n, description);
}
Prints "654321
is odd"
```

Perhaps most surprisingly, the break keyword also returns a value. This can be used to allow "infinite" loops to return values:

```
fn main() {
  let n = loop {
     break 123;
  };

  println!("{}", n);
}
Prints "123"
```

Flow control 51

You may wonder what parts of Rust are *not* expressions and, thus, do not return values. Statements are not expressions. These appear in Rust in three places:

- Expressions delimited by the semicolon (;)
- Binding a name to a value with the assignment operator (=)
- Type declarations, which include functions (fn) and data types created with the struct and enum keywords

Formally, the first form is referred to as an *expression statement*. The last two are both called *declaration statements*. In Rust, no value is represented as () (the "unit" type).

2.4.7 Match: Type-aware pattern matching

While it's possible to use if/else blocks in Rust, match provides a safer alternative. match warns you if you haven't considered a relevant alternative. It is also elegant and concise:

match offers a sophisticated and concise syntax for testing multiple possible values. Some examples are

- Inclusive ranges (10 . . = 20) to match any value within the range.
- A Boolean OR (|) will match when either side matches.
- The underscore () to match everything.

match is analogous to the switch keyword in other languages. Unlike C's switch, however, match guarantees that all possible options for a type are explicitly handled. Failing to provide a branch for every possible value triggers a compiler error. Additionally, a match does not "fall through" to the next option by default. Instead, match returns immediately when a match is found.

Listing 2.8 demonstrates a larger example of match. The source code for this listing is in ch2/ch2-match-needles.rs. The code prints these two lines to the screen:

```
42: hit!
132: hit!
```

Listing 2.8 Using match to match multiple values

```
The variable needle
 1 fn main() {
                              is now redundant.
    let needle = 42;
    let haystack = [1, 1, 2, 5, 14, 42, 132, 429, 1430, 4862];
 3
                                          This match expression returns a value
 5
    for item in &haystack {
                                        that can be bound to a variable.
 6
     let result = match item {
       42 | 132 => "hit!", <----
 7
                                         Success! 42 | 132 matches
        _ => "miss",
                                       both 42 and 132.
 9
                                     A wildcard pattern that
10
     if result == "hit!" {
                                    matches everything
11
       println!("{}: {}", item, result);
13
14
    }
15 }
```

The match keyword plays an important role within the Rust language. Many control structures (like looping) are defined in terms of match under the hood. These really shine when combined with the Option type that's discussed in depth in the next chapter.

Now that we have taken a good look at defining numbers and working with some of Rust's flow control mechanisms, let's move on to adding structure to programs with functions.

2.5 Defining functions

Looking back to where the chapter begins, the snippet in listing 2.2 contained a small function, add(). add takes two i32 values and returns their sum. The following listing repeats the function.

Listing 2.9 Defining a function (extract of listing 2.2)

```
10 fn add(i: i32, j: i32) -> i32 {
    add() takes two integer parameters and returns an integer. The two arguments are bound to the local variables i and j.
```

For the moment, let's concentrate on the syntax of each of the elements in listing 2.9. Figure 2.2 provides a visual picture of each of the pieces. Anyone who has programmed in a strongly-typed programming language should be able to squint their way through the diagram.

Rust's functions require that you specify your parameter's types and the function's return type. This is the foundational knowledge that we'll need for the majority of our work with Rust. Let's put it to use with our first non-trivial program.

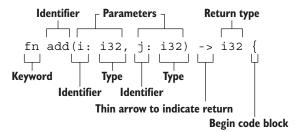

Figure 2.2 Rust's function definition syntax

2.6 Using references

If you have only used a dynamic programming language so far in your career, the syntax and semantics of references can be frustrating. It can be difficult to form a mental picture of what is happening. That makes it difficult to understand which symbols to put where. Thankfully, the Rust compiler is a good coach.

A *reference* is a value that stands in place for another value. For example, imagine that variable a is a large array that is costly to duplicate. In some sense, a reference r is a cheap copy of a. But instead of creating a duplicate, the program stores a's address in memory. When the data from a is required, r can be *dereferenced* to make a available. The following listing shows the code for this.

Listing 2.10 Creating a reference to a large array

```
fn main() {
  let a = 42;
  let r = &a;
  let b = a + *r;

println!("a + a = {}", b);

Prints "a + a = 84"
}

r is a reference to a.

Adds a to a (via dereferencing r) and assigns it to b
```

References are created with the *reference operator* (&) and dereferencing occurs with the *dereference operator* (*). These operators act as *unary operators*, meaning that these only take one operand. One of the limitations of source code written in ASCII text is that multiplication and dereferencing use the same symbol. Let's see these in use as part of a larger example.

Listing 2.11 searches for a number (the needle defined on line 2) within an array of numbers (the haystack defined on line 3). The code then prints 42 to the console when compiled. The code for this listing is in ch2/ch2-needle-in-haystack.rs.

Listing 2.11 Searching for an integer in an array of integers

```
6    if *item == needle {
7         println!("{}", item);
8     }
9    }
10 }
The syntax *item returns the item's referent.
```

Each iteration changes the value of item to refer to the next item within haystack. On the first iteration, *item returns 1, and on the last, it returns 21147.

2.7 Project: Rendering the Mandelbrot set

So far, we haven't learned much Rust, but we already have the tools to create some interesting pictures of fractals. So let's do that now with listing 2.12. To begin

- 1 In a terminal window, execute the following commands to create a project that can render the Mandelbrot set:
 - a cd \$TMP (or cd %TMP% on MS Windows) to move to a directory that's not critical.
 - b cargo new mandelbrot --vcs none creates a new blank project.
 - c cd mandelbrot moves into the new project root.
 - d cargo add num to edit Cargo.toml, adding the num crate as a dependency (see the sidebar entitled "2.2" in section 2.3.4 for instructions to enable this cargo feature).
- 2 Replace src/main.rs with the code in listing 2.12, which you'll also find in ch2/ch2-mandelbrot/src/main.rs.
- 3 Execute cargo run. You should see the Mandelbrot set rendered in the terminal:

      y min: f64,
                             members of the set
 9
      y max: f64,
     width: usize,
10
                                    Parameters that represent the
11
      height: usize,
                                    size of the output in pixels
                                                                          Creates a container
12
      ) -> Vec<Vec<usize>> {
                                                                          to house the data
13
                                                                         from each row
14
      let mut rows: Vec<_> = Vec::with_capacity(width);
15
      for img y in 0..height {
                                                                            Iterates row by row,
16
                                                                            allowing us to print
17
        let mut row: Vec<usize> = Vec::with capacity(height);
                                                                            the output line by line
18
        for img x in 0..width {
19
          let x percent = (img x as f64 / width as f64);
                                                                                   Calculates the
20
          let y percent = (img y as f64 / height as f64);
                                                                                   proportion of the
21
                                                                                   space covered in
          let cx = x min + (x max - x min) * x percent;
22
                                                                                   our output and
23
          let cy = y min + (y max - y min) * y percent;
                                                                                   converts that to
24
          let escaped at = mandelbrot at point(cx, cy, max iters);
                                                                                   points within the
25
          row.push(escaped at);
                                                                                   search space
26
27
28
        all rows.push(row);
29
30
      rows
                                          Called at every pixel
31 }
                                          (e.g., every row and column
32
                                          that's printed to stdout)
33 fn mandelbrot at point(
34
      cx: f64,
                                                                   Initializes a complex
     cy: f64,
35
                                                                   number at the origin with
36
      max iters: usize,
                                                                   real (re) and imaginary
37
      ) -> usize {
                                                                   (im) parts at 0.0
38
      let mut z = Complex { re: 0.0, im: 0.0 };
39
      let c = Complex::new(cx, cy);
                                                     Initializes a complex number from the
40
                                                    coordinates provided as function arguments
      for i in 0..=max iters {
41
42
        if z.norm() > 2.0 {
                                           Checks the escape condition and calculates
43
          return i;
                                           the distance from the origin (0, 0), an
44
                                           absolute value of a complex number
45
                                      Repeatedly mutates z to check whether
46
                                     c lies within the Mandelbrot set
47
      max iters
48 }
                            As i is no longer in scope, we fall back to max iters.
49
```

```
50 fn render mandelbrot (escape vals: Vec<Vec<usize>>) {
51 for row in escape vals {
     let mut line = String::with capacity(row.len());
     for column in row {
54
       let val = match column {
55
         0..=2 => ' ',
         2..=5 => '.',
56
57
         5..=10 => '•',
         11..=30 => '*',
59
          30..=100 => '+',
         100..=200 => 'x',
60
61
         200..=400 => '$',
         400..=700 => '#',
62
63
          _ => '%',
       };
65
66
       line.push(val);
67
      println!("{}", line);
68
69
    }
70 }
71
72 fn main() {
    let mandelbrot = calculate mandelbrot(1000, 2.0, 1.0, -1.0,
                                         1.0, 100, 24);
74
75
76
    render mandelbrot (mandelbrot);
77 }
```

So far in this section, we've put the basics of Rust into practice. Let's continue our exploration by learning how to define functions and types.

2.8 Advanced function definitions

Rust's functions can get somewhat scarier than the add(i: i32, j: i32) -> i32 from listing 2.2. To assist those who are reading more Rust source code than writing it, the following sections provide some extra content.

2.8.1 Explicit lifetime annotations

As a bit of forewarning, allow me to introduce some more complicated notation. As you read through Rust code, you might encounter definitions that are hard to decipher because those look like hieroglyphs from an ancient civilizations. Listing 2.13 provides an extract from listing 2.14 that shows one such example.

Listing 2.13 A function signature with explicit lifetime annotations

```
1 fn add_with_lifetimes<'a, 'b>(i: &'a i32, j: &'b i32) -> i32 {
2  *i + *j
3 }
```

Like all unfamiliar syntax, it can be difficult to know what's happening at first. This improves with time. Let's start by explaining *what* is happening, and then go on to

discuss *why* it is happening. The following bullet points break line 1 of the previous snippet into its parts:

- fn add_with_lifetimes(...) -> i32 should be familiar to you already. From this we can infer that add_with_lifetimes() is a function that returns an i32 value.
- <'a, 'b> declares two lifetime variables, 'a and 'b, within the scope of add with lifetimes(). These are normally spoken as *lifetime a* and *lifetime b*.
- i: &'a i32 binds lifetime variable 'a to the lifetime of i. The syntax reads as "parameter i is a reference to an i32 with lifetime a."
- j: &'b i32 binds the lifetime variable 'b to the lifetime of j. The syntax reads as "parameter j is a reference to an i32 with lifetime b."

The significance of binding a lifetime variable to a value probably isn't obvious. Underpinning Rust's safety checks is a lifetime system that verifies that all attempts to access data are valid. Lifetime annotations allow programmers to declare their intent. All values bound to a given lifetime must live as long as the last access to any value bound to that lifetime.

The lifetime system usually works unaided. Although every parameter has a lifetime, these checks are typically invisible as the compiler can infer most lifetimes by itself. But the compiler needs assistance in difficult cases. Functions that accept multiple references as arguments or return a reference are often when the compiler will request assistance via an error message.

No lifetime annotations are required when calling a function. When used in a complete example as in the next listing, you can see lifetime annotations at the function definition (line 1), but not when it's used (line 8). The source code for the listing is in ch2-add-with-lifetimes.rs.

Listing 2.14 Type signature of a function with lifetime explicit annotations

```
1 fn add with lifetimes<'a, 'b>(i: &'a i32, j: &'b i32) -> i32 {
    *i + *j
                          Adds the values referred to by
 3 }
                          i and j rather than adding the
 4
                         references directly
 5 fn main() {
 6 let a = 10;
                                                          &10 and &20 mean reference
 7
    let b = 20;
                                                         10 and 20, respectively. No
   let res = add with lifetimes(&a, &b);
                                                          lifetime notation is required
                                                        when calling a function.
10 println!("{}", res);
11 }
```

On line 2, *i + *j adds together the referent values held by the i and j variables. It's common to see lifetime parameters when using references. While Rust can infer lifetimes

⁶ Omitting lifetime annotations is formally referred to as *lifetime elision*.

in other cases, references require the programmer to specify the intent. Using two lifetime parameters (a and b) indicates that the lifetimes of i and j are decoupled.

NOTE Lifetime parameters are a way of providing control to the programmer while maintaining high-level code.

2.8.2 Generic functions

Another special case of function syntax appears when programmers write Rust functions to handle many possible input types. So far, we have seen functions that accept 32-bit integers (i32). The following listing shows a function signature that can be called by many input types as long as these are all the same.

Listing 2.15 Type signature of a generic function

Capital letters in place of a type indicate a *generic type*. Conventionally, the variables T, U, and V are used as placeholder values, but this is arbitrary. E is often used to denote an error type. We'll look at error handling in detail in chapter 3.

Generics enable significant code reuse and can greatly increase the usability of a strongly-typed language. Unfortunately, listing 2.15 doesn't compile as is. The Rust compiler complains that it cannot add two values of any type T together. The following shows the output produced when attempting to compile listing 2.15:

This issue arises because T really means any type at all, even types where addition is not supported. Figure 2.3 provides a visual representation of the problem. Listing 2.15 attempts to refer to the outer ring, whereas addition is only supported by types within the inner ring.

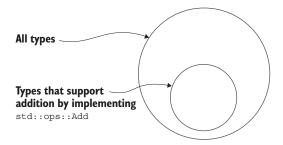

Figure 2.3 Only a subset of types have implement operators. When creating generic functions that include such an operator, that operation's trait must be included as a trait bound.

How do we specify that type T must implement addition? Answering this requires introducing some new terminology.

All of Rust's operators, including addition, are defined within *traits*. To require that type T must support addition, we include a trait bound alongside the type variable in the function's definition. The following listing gives an example of this syntax.

Listing 2.16 Type signature of a generic function with trait bounds

```
fn add<T: std::ops::Add<Output = T>>(i: T, j: T) -> T {
   i + j
}
```

The fragment <T: std::ops::Add<Output = T>> says that T must implement std::ops::Add. Using a single type variable T with the trait bound ensures that arguments i and j, as well as the result type, are the same type and that their type supports addition.

What is a trait? A *trait* is a language feature that is analogous to an interface, protocol, or contract. If you have a background in object-oriented programming, consider a trait to be an abstract base class. If you have a background in functional programming, Rust's traits are close to Haskell's type classes. For now, it's enough to say that traits enable types to advertise that they are using common behavior.

All of Rust's operations are defined with traits. For example, the addition operator (+) is defined as the std::ops::Add trait. Traits are properly introduced in chapter 3 and are progressively explained in depth during the course of the book.

To reiterate: all of Rust's operators are syntactic sugar for a trait's methods. Rust supports operator overloading this way. During the compilation process, a + b is converted to a.add(b).

Listing 2.17 is a full example that demonstrates that generic functions can be called by multiple types. The listing prints these three lines to the console:

```
4.6
30
15s
```

Listing 2.17 A generic function with a type variable and trait bounds

```
Brings the Add trait from
            std::ops into local scope
                                            Brings the Duration
                                            type from std::time
 1 use std::ops::{Add};
                                                                   The arguments to add()
                                            into local scope
 2 use std::time::{Duration};
                                                                   can accept any type
                                                                   that implements
                                                                   std::ops::Add.
 4 fn add<T: Add<Output = T>>(i: T, j: T) -> T {
                                                Calls add() with
 6 }
                                                floating-point values
 7
 8 fn main() {
                                                  Calls add() with
    let floats = add(1.2, 3.4);
                                                 integer values
10 let ints = add(10, 20);
11 let durations = add(
                                     Calls add() with Duration values, representing
12
      Duration::new(5, 0),
                                     a duration between two points in time
      Duration::new(10, 0)
13
14
    );
                                                  Because std::time::Duration does
15
    println!("{}", floats);
                                                  not implement the std::fmt::Display
16
                                                  trait, we can fall back to requesting
    println!("{}", ints);
17
                                               std::fmt::Debug.
    println!("{:?}", durations);
18
19
20 }
```

As you can see, function signatures can become somewhat convoluted. Interpreting these can take some patience. Hopefully, you now have the tools to break the pieces apart in case you get stuck down the track. Here are a few principles that should assist you when reading Rust code:

- Terms in lowercase (i, j) denote variables.
- Single uppercase letters (T) denote generic type variables.
- Terms beginning with uppercase (Add) are either traits or concrete types, such as String or Duration.
- Labels ('a) denote lifetime parameters.

2.9 Creating grep-lite

We've spent most of the chapter discussing numbers. It's time for another practical example. We'll use it to learn a little bit about how Rust handles text.

Listing 2.18 is our first iteration of grep-lite. The code for this program is in the ch2-str-simple-pattern.rs file. Its hard-coded parameters restrict flexibility somewhat, but these are useful illustrations of string literals. The code prints a line to the console:

dark square is a picture feverishly turned -- in search of what?

Listing 2.18 Searching for a simple pattern within lines of a string

```
1 fn main() {
2  let search_term = "picture";
```

```
3 let quote = "\
 4 Every face, every shop, bedroom window, public-house, and
 5 dark square is a picture feverishly turned--in search of what?
 6 It is the same with books.
 7 What do we seek through millions of pages?";
                                                               Multilined strings do not
 8
                                                               require special syntax.
9 for line in quote.lines() {
                                                               The \ character on line 3
10    if line.contains(search term) {
                                                               escapes the new line.
         println!("{}", line);
11
                                                lines() returns an iterator over quote
12
13 }
                                                where each iteration is a line of text. Rust
                                                uses each operating system's conventions
14 }
                                                on what constitutes a new line.
```

As you can see, Rust's strings can do quite a lot by themselves. Some features of listing 2.18 that are worth highlighting include the following. From here, we'll expand the functionality of our proto-application:

- Line 9 (quote.lines()) demonstrates iterating line-by-line in a platform-independent manner.
- Line 10 (line.contains()) demonstrates searching for text using the method syntax.

Navigating Rust's rich collection of string types

Strings are complicated for newcomers to Rust. Implementation details tend to bubble up from below and make comprehension difficult. How computers represent text is complicated, and Rust chooses to expose some of that complexity. This enables programmers to have full control but does place a burden on those learning the language.

String and &str both represent text, yet are distinct types. Interacting with values from both types can be an annoying exercise at first as different methods are required to perform similar actions. Prepare yourself for irritating type errors as your intuition develops. Until that intuition develops, however, you will usually have fewer issues if you convert your data to the String type.

A String is (probably) closest to what you know as a string type from other languages. It supports familiar operations such as concatenation (joining two strings together), appending new text onto an existing string, and trimming whitespace.

str is a high-performance, relatively feature-poor type. Once created, str values cannot expand or shrink. In this sense, these are similar to interacting with a raw memory array. Unlike a raw memory array, though, str values are guaranteed to be valid UTF-8 characters.

str is usually seen in this form: &str. A &str (pronounced string slice) is a small type that contains a reference to str data and a length. Attempting to assign a variable to type str will fail. The Rust compiler wants to create fixed-sized variables within a function's stack frame. As str values can be of arbitrary length, these can only be stored as local variables by reference.

(continued)

For those readers that have prior experience with systems programming, String uses dynamic memory allocation to store the text that it represents. Creating &str values avoids a memory allocation.

String is an owned type. Ownership has a particular meaning within Rust. An owner is able to make any changes to the data and is responsible for deleting values that it owns when it leaves scope (this is fully explained in chapter 3). A &str is a borrowed type. In practical terms, this means that &str can be thought of as read-only data, whereas String is read-write.

String literals (e.g., "Rust in Action") have the type &str. The full type signature including the lifetime parameter is &'static str. The 'static lifetime is somewhat special. It too owes its name to implementation details. Executable programs can contain a section of memory that is hard-coded with values. That section is known as static memory because it is read-only during execution.

Some other types may be encountered in your travels. Here's a short list:^a

- char—A single character encoded as 4 bytes. The internal representation of char is equivalent to UCS-4/UTF-32. This differs from &str and String, which encodes single characters as UTF-8. Conversion does impose a penalty, but it means that char values are of fixed-width and are, therefore, easier for the compiler to reason about. Characters encoded as UTF-8 can span 1 to 4 bytes.
- [u8]—A slice of raw bytes, usually found when dealing with streams of binary data.
- Vec<u8>—A vector of raw bytes, usually created when consuming [u8] data.
 String is to Vec<u8> as str is to [u8].
- std::ffi::OSString—A platform-native string. It's behavior is close to String but without a guarantee that it's encoded as UTF-8 and that it won't contain the zero byte (0x00).
- std::path::Path—A string-like type that is dedicated to handling filesystem paths.

Fully understanding the distinction between String and &str requires knowledge of arrays and vectors. Textual data is similar to these two types with added convenience methods applied over the top.

Let's start adding functionality to grep-lite by printing the line number along with the match. This is equivalent to the -n option within the POSIX.1-2008 standard for the grep utility (http://mng.bz/ZPdZ).

Adding a few lines to our previous example, we now see the following line printed to the screen. Listing 2.19 shows the code that adds this functionality, which you'll find in ch2/ch2-simple-with-linenums.rs:

2: dark square is a picture feverishly turned--in search of what?

Unfortunately, this is not an exhaustive list. Specific use cases sometimes require special handling.

Listing 2.19 Manually incrementing an index variable

```
1 fn main() {
                                            A backslash escapes the newline
     let search term = "picture";
                                            character in the string literal.
     let quote = "\
 4 Every face, every shop, bedroom window, public-house, and
 5 dark square is a picture feverishly turned--in search of what?
 6 It is the same with books. What do we seek through millions of pages?";
 7
     let mut line num: usize = 1;
                                                  Declares line num as mutable via
 8
                                                  let mut and initializes it with 1
    for line in quote.lines() {
 9
      if line.contains(search term) {
10
         println!("{}: {}", line_num, line);
11
                                                           Updates the println!
12
                                                           macro to allow for both
13
       line num += 1;
                                                           values to be printed
                                  Increments
14
                                  line num in place
15 }
```

Listing 2.20 shows a more ergonomic approach to incrementing \mathtt{i} . The output is the same, but here the code makes use of the enumerate() method and method chaining. enumerate() takes an iterator \mathtt{I} , returning another (\mathtt{N} , \mathtt{I}), where \mathtt{N} is a number that starts at 0 and increments by 1 each iteration. The source code for this listing can be found in ch2/ch2-simple-with-enumerate.rs.

Listing 2.20 Automatically incrementing an index variable

```
1 fn main() {
     let search term = "picture";
     let quote = "\
 4 Every face, every shop, bedroom window, public-house, and
 5 dark square is a picture feverishly turned--in search of what?
 6 It is the same with books. What do we seek through millions of pages?";
 7
    for (i, line) in quote.lines().enumerate() {
 8
                                                                Because lines()
 9
     if line.contains(search term) {
                                                                returns an iterator.
        let line num = i + 1;
1.0
                                                                it can be chained
         println!("{}: {}", line num, line);
11
                                                                with enumerate().
12
                  Performs addition to calculate the line
13 }
               number, avoiding calculations at every step
14 }
```

Another feature of grep that is extremely useful is to print some context before and after the line that matches. In the GNU grep implementation, this is the -C NUM switch. To add support for that feature in grep-lite, we need to be able to create lists.

2.10 Making lists of things with arrays, slices, and vectors

Lists of things are incredibly common. The two types that you will work with most often are *arrays* and *vectors*. Arrays are fixed-width and extremely lightweight. Vectors are growable but incur a small runtime penalty because of the extra bookkeeping that

these do. To understand the underlying mechanisms with text data in Rust, it helps to have a cursory understanding of what is happening.

The goal of this section is to support printing out n lines of context that surround a match. To get there, we need to segue somewhat and explain more fully arrays, slices, and vectors. The most useful type for this exercise is the vector. To learn about vectors, though, we need to start by learning about its two simpler cousins: arrays and slices.

2.10.1 Arrays

An *array*, at least as far as Rust is concerned, is a tightly-packed collection of the same thing. It's possible to replace items within an array, but its size cannot change. Because variable-length types like String add a degree of complication, we'll revert back to discussing numbers for a little while.

Creating arrays takes two forms. We can provide a comma-delimited list within square brackets (for example, [1, 2, 3]) or a *repeat expression*, where you furnish two values delimited by a semicolon (for example, [0; 100]). The value on the left (0) is repeated by the number of times on the right (100). Listing 2.21 shows each variation on lines 2–5. The source code for this listing is in the ch2-3arrays.rs file. It prints these four lines to the console:

Listing 2.21 Defining arrays and iterating over their elements

```
1 fn main() {
 2 let one
                       = [1, 2, 3];
   let two: [u8; 3] = [1, 2, 3];
 4 let blank1 = [0; 3];
   let blank2: [u8; 3] = [0; 3];
 5
 7
    let arrays = [one, two, blank1, blank2];
 8
9
   for a in &arrays {
10
    print!("{:?}: ", a);
     for n in a.iter() {
11
       print!("\t{} + 10 = {}", n, n+10);
12
13
14
15
      let mut sum = 0;
16
     for i in 0..a.len() {
17
       sum += a[i];
18
19
     println!("\t(\Sigma{:?} = {})", a, sum);
20
21 }
```

Arrays are a simple data structure from the machine's point of view. These are a contiguous block of memory with elements of a uniform type. The simplicity is still somewhat deceptive. Arrays can cause a few learning difficulties for newcomers:

- The notation can be confusing. [T; n] describes an array's type, where T is the elements' type and n is a non-negative integer. [f32; 12] denotes an array of 12 32-bit floating-point numbers. It's easy to get confused with slices [T], which do not have a compile-time length.
- [u8; 3] is a different type than [u8; 4]. The size of the array matters to the type system.
- In practice, most interaction with arrays occurs via another type called a slice ([T]). The slice is itself interacted with by reference (&[T]). And to add some linguistic confusion into the mix, both slices and references to slices are called *slices*.

Rust maintains its focus on safety. Array indexing is bounds checked. Requesting an item that's out of bounds crashes (*panics* in Rust terminology) the program rather than returning erroneous data.

2.10.2 Slices

Slices are dynamically sized array-like objects. The term *dynamically sized* means that their size is not known at compile time. Yet, like arrays, these don't expand or contract. The use of the word *dynamic* in dynamically sized is closer in meaning to *dynamic typing* rather than movement. The lack of compile-time knowledge explains the distinction in the type signature between an array ([T; n]) and a slice ([T]).

Slices are important because it's easier to implement traits for slices than arrays. Traits are how Rust programmers add methods to objects. As [T; 1], [T; 2], ..., [T; n] are all different types, implementing traits for arrays can become unwieldy. Creating a slice from an array is easy and cheap because it doesn't need to be tied to any specific size.

Another important use for slices is their ability to act as a view on arrays (and other slices). The term *view* here is taken from database technology and means that slices can gain fast, read-only access to data without needing to copy anything around.

The problem with slices is that Rust wants to know the size of every object in your program, and slices are defined as not having a compile-time size. References to the rescue. As mentioned in the discussion about the use of the term dynamically sized, slice size is fixed in memory. These are made up of two usize components (a pointer and a length). That's why you typically see slices referred to in their referenced form, &[T] (like string slices that take the notation &str).

NOTE Don't worry too much about the distinctions between arrays and slices yet. In practice, it's not material. Each term is an artifact of implementation details. Those implementation details are important when dealing with performance-critical code but not when learning the basics of the language.

2.10.3 Vectors

Vectors (Vec<T>) are growable lists of T. Using vectors is extremely common in Rust code. These incur a small runtime penalty compared to arrays because of the extra bookkeeping that must be done to enable their size to change over time. But vectors almost always make up for this with their added flexibility.

The task at hand is to expand the feature set of the grep-lite utility. Specifically, we want the ability to store n lines of context around a match. Naturally, there are many ways to implement such a feature.

To minimize code complexity, we'll use a two-pass strategy. In the first pass, we'll tag lines that match. During the second pass, we'll collect lines that are within n lines of each of the tags.

The code in listing 2.22 (available at ch2/ch2-introducing-vec.rs) is the longest you've seen so far. Take your time to digest it.

The most confusing syntax in the listing is probably Vec<Vec<(usize, String)>>, which appears on line 15. Vec<Vec<(usize, String)>> is a vector of vectors (e.g., Vec<Vec<T>>), where T is a pair of values of type (usize, String). (usize, String) is a tuple that we'll use to store line numbers along with the text that's a near match. When the needle variable on line 3 is set to "oo", the following text is printed to the console:

```
1: Every face, every shop,
2: bedroom window, public-house, and
3: dark square is a picture
4: feverishly turned--in search of what?
3: dark square is a picture
4: feverishly turned--in search of what?
5: It is the same with books.
6: What do we seek
7: through millions of pages?
```

Listing 2.22 Enabling context lines to be printed out with a Vec<Vec<T>>

```
1 fn main() {
 2 let ctx lines = 2;
     let needle = "oo";
 4 let haystack = "\
                                                     tags holds line
 5 Every face, every shop,
                                                     numbers where
 6 bedroom window, public-house, and
                                                     matches occur.
 7 dark square is a picture
 8 feverishly turned -- in search of what?
                                                         ctx contains a vector
 9 It is the same with books.
                                                         per match to hold the
10 What do we seek
                                                         context lines.
11 through millions of pages?";
12
                                                                 Iterates through the
13
     let mut tags: Vec<usize> = vec![];
                                                                 lines, recording line
   let mut ctx: Vec<Vec<(
14
                                                                 numbers where
                   usize, String) >> = vec![];
                                                                 matches are
16
                                                                 encountered
    for (i, line) in haystack.lines().enumerate() {
```

```
if line.contains(needle) {
18
                                                                            Vec::with capacity(n)
19
          tags.push(i);
                                                                            reserves space for n
2.0
                                                                           items. No explicit type
21
          let v = Vec::with capacity(2*ctx lines + 1);
                                                                           signature is required
                                                                            as it can be inferred
22
          ctx.push(v);
                                                                           via the definition of
23
                                                                            ctx on line 15.
24
                                        When there are no
25
                                        matches, exits early
26
     if tags.is empty() {
                                                                          For each tag, at every
27
        return:
                                                                          line, checks to see if
28
                                                                          we are near a match.
29
                                                                          When we are, adds
     for (i, line) in haystack.lines().enumerate() {
30
                                                                          that line to the
        for (j, tag) in tags.iter().enumerate() {
31
                                                                           relevant Vec < T >
32
          let lower bound =
                                                                          within ctx.
33
               tag.saturating sub(ctx lines);
34
          let upper bound =
                                                                         saturating sub() is
35
               tag + ctx lines;
                                                                         subtraction that returns
36
                                                                         0 on integer underflow
37
          if (i >= lower_bound) && (i <= upper_bound) {</pre>
                                                                         rather than crashing the
38
               let line as string = String::from(line);
                                                                         program (CPUs don't like
39
               let local ctx = (i, line as string);
                                                                         attempting to send usize
40
               ctx[j].push(local ctx);
                                                                        below zero).
41
42
                                                                       Copies line into a new
43
                                                                       String and stores that
44
                                                                       locally for each match
     for local ctx in ctx.iter() {
45
46
        for &(i, ref line) in local ctx.iter() {
                                                                   ref line informs the compiler
47
         let line num = i + 1;
                                                                   that we want to borrow this
          println!("{}: {}", line num, line);
48
                                                                   value rather than move it.
49
                                                                   These two terms are explained
50
                                                                   fully in later chapters.
51 }
```

Vec<T> performs best when you can provide it with a size hint via Vec::with_capacity(). Providing an estimate minimizes the number of times memory will need to be allocated from the OS.

NOTE When considering this approach in real text files, encodings can cause issues. String is guaranteed to be UTF-8. Naively reading in a text file to a String causes errors if invalid bytes are detected. A more robust approach is to read in data as [u8] (a slice of u8 values), then decode those bytes with help from your domain knowledge.

2.11 Including third-party code

Incorporating third-party code is essential to productive Rust programming. Rust's standard library tends to lack many things that other languages provide, like random number generators and regular expression support. That means it's common to incorporate third-party crates into your project. To get your feet wet, let's start with the regex crate.

Crates are the name the Rust community uses where others use terms such as package, distribution, or library. The regex crate provides the ability to match regular expressions rather than simply looking for exact matches.

To use third-party code, we'll rely on the cargo command-line tool. Follow these instructions:

- 1 Open a command prompt.
- 2 Move to a scratch directory with cd /tmp (cd %TMP% on MS Windows).
- 3 Run cargo new grep-lite --vcs none. It produces a short confirmation message:

```
Created binary (application) `grep-lite` package
```

- 4 Run cd grep-lite to move into the project directory.
- 5 Execute cargo add regex@1 to add version 1 of the regex crate as a dependency. This alters the file /tmp/grep-lite/Cargo.toml. If cargo add is unavailable for you, see the sidebar, "2.2," in section 2.3.4.
- 6 Run cargo build. You should see output fairly similar to the following begin to appear:

```
Updating crates.io index

Downloaded regex v1.3.6

Compiling lazy_static v1.4.0

Compiling regex-syntax v0.6.17

Compiling thread_local v1.0.1

Compiling aho-corasick v0.7.10

Compiling regex v1.3.6

Compiling grep-lite v0.1.0 (/tmp/grep-lite)

Finished dev [unoptimized + debuginfo] target(s) in 4.47s
```

Now that you have the crate installed and compiled, let's put it into action. First, we'll support searching for exact matches in listing 2.23. Later, in listing 2.26, the project grows to support regular expressions.

2.11.1 Adding support for regular expressions

Regular expressions add great flexibility to the patterns that we are able to search for. The following listing is a copy of an early example that we'll modify.

Listing 2.23 Matching on exact strings with the contains () method

```
}
}
}
```

Make sure that you have updated grep-lite/Cargo.toml to include regex as a dependency as described in the previous section. Now, open grep-lite/src/main.rs in a text editor and fill it in with the code in the following listing. The source code for this listing is available in ch2/ch2-with-regex.rs.

Listing 2.24 Searching for patterns with regular expressions

```
use regex::Regex;
                                                                 unwrap() unwraps a Result,
                              Brings the Regex type from the
                                                                 crashing if an error occurs.
                              regex crate into local scope
                                                                 Handling errors more robustly
fn main() {
                                                                 is discussed in depth later in
  let re = Regex::new("picture").unwrap();
                                                                 the book.
  let quote = "Every face, every shop, bedroom window, public-house, and
dark square is a picture feverishly turned--in search of what?
It is the same with books. What do we seek through millions of pages?";
                                                        Replaces the contains() method
                                                        from listing 2.23 with a match block
  for line in quote.lines() {
                                                       that requires that we handle all
    let contains substring = re.find(line);
                                                     possible cases
    match contains_substring {
         Some() => println!("{}", line),
                                                         Some(T) is the positive case of an
         None => (), <─
                                                         Option, meaning that re.find() was
                              None is the negative
                                                         successful: it matches all values.
                              case of an Option; () can
  }
                              be thought of as a null
}
                               placeholder value here.
```

Open a command prompt and move to the root directory of your grep-lite project. Executing cargo run should produce output similar to the following text:

```
$ cargo run
   Compiling grep-lite v0.1.0 (file:///tmp/grep-lite)
   Finished dev [unoptimized + debuginfo] target(s) in 0.48s
   Running `target/debug/grep-lite`
dark square is a picture feverishly turned--in search of what?
```

Admittedly, the code within listing 2.24 hasn't taken significant advantage of its new-found regular expression capabilities. Hopefully, you'll have the confidence to be able to slot those into some of the more complex examples.

2.11.2 Generating the third-party crate documentation locally

Documentation for third-party crates is typically available online. Still, it can be useful to know how to generate a local copy in case the internet fails you:

1 Move to the root of the project directory in a terminal: /tmp/grep-lite or %TMP%\grep-lite

2 Execute cargo doc. It will inform you of its progress in the console:

\$ cargo doc Checking lazy_static v1.4.0 Documenting lazy_static v1.4.0 Checking regex-syntax v0.6.17 Documenting regex-syntax v0.6.17 Checking memchr v2.3.3 Documenting memchr v2.3.3 Checking thread_local v1.0.1 Checking aho-corasick v0.7.10 Documenting thread_local v1.0.1 Documenting aho-corasick v0.7.10 Checking regex v1.3.6 Documenting grep-lite v0.1.0 (file:///tmp/grep-lite) Finished dev [unoptimized + debuginfo] target(s) in 3.43s

Congratulations. You have now created HTML documentation. By opening /tmp/grep-lite/target/doc/grep_lite/index.html in a web browser (also try cargo doc --open from the command line), you'll be able to view the documentation for all the crates that yours depend on. It's also possible to inspect the output directory to take a look at what is available to you:

2.11.3 Managing Rust toolchains with rustup

rustup is another handy command-line tool, along with cargo. Where cargo manages projects, rustup manages your Rust installation(s). rustup cares about Rust toolchains and enables you to move between versions of the compiler. This means it's possible to compile your projects for multiple platforms and experiment with nightly features of the compiler while keeping the stable version nearby.

rustup also simplifies accessing Rust's documentation. Typing rustup doc opens your web browser to a local copy of Rust's standard library.

2.12 Supporting command-line arguments

Our program is rapidly increasing its feature count. Yet, there is no way for any options to be specified. To become an actual utility, grep-lite needs to be able to interact with the world.

Sadly, though, Rust has a fairly tight standard library. As with regular expressions, another area with relatively minimalist support is handling command-line arguments. A nicer API is available through a third-party crate called clap (among others).

Now that we've seen how to bring in third-party code, let's take advantage of that to enable users of grep-lite to choose their own pattern. (We'll get to choosing their own input source in the next section.) First, add clap as a dependency in your Cargo.toml:

```
$ cargo add clap@2
    Updating 'https://github.com/rust-lang/crates.io-index' index
    Adding clap v2 to dependencies
```

You can confirm that the crate has been added to your project by inspecting its Cargo.toml file.

Listing 2.25 Adding a dependency to grep-lite/Cargo.toml

```
[package]
name = "grep-lite"
version = "0.1.0"
authors = ["Tim McNamara <author@rustinaction.com>"]
[dependencies]
regex = "1"
clap = "2"
```

Now, adjust src/main.rs.

Listing 2.26 Editing grep-lite/src/main.rs

```
Brings clap::App and
 1 use regex::Regex;
 2 use clap::{App,Arg};
                                   clap::Arg objects into
                                   local scope
 4 fn main() {
 5 let args = App::new("grep-lite")
                                                  Incrementally builds a command
 6
      .version("0.1")
                                                  argument parser, where each
 7
      .about("searches for patterns")
                                                  argument takes an Arg. In our
 8
      .arg(Arg::with name("pattern")
                                                  case, we only need one.
       .help("The pattern to search for")
 9
       .takes_value(true)
10
11
         .required(true))
12
      .get matches();
                                                                 Extracts the
13
                                                                 pattern argument
14
     let pattern = args.value of("pattern").unwrap();
     let re = Regex::new(pattern).unwrap();
15
16
17
     let quote = "Every face, every shop, bedroom window, public-house, and
18 dark square is a picture feverishly turned--in search of what?
19 It is the same with books. What do we seek through millions of pages?";
21
     for line in quote.lines() {
22 match re.find(line) {
```

With your project updated, executing cargo run should set off a few lines in your console:

The error is due to the fact that we haven't passed sufficient arguments through to our resulting executable. To pass arguments through, cargo supports some special syntax. Any arguments appearing after -- are sent through to the resulting executable binary:

```
$ cargo run -- picture
    Finished dev [unoptimized + debuginfo] target(s) in 0.0 secs
    Running `target/debug/grep-lite picture`
dark square is a picture feverishly turned--in search of what?
```

But clap does more than provide parsing. It also generates usage documentation on your behalf. Running grep-lite --help provides an expanded view:

2.13 Reading from files

Searching for text wouldn't be complete without being able to search within files. File I/O can be surprisingly finicky and so has been left until last.

Before adding this functionality to grep-lite, let's take a look at a standalone example in listing 2.27. The code for this listing is in the ch2-read-file.rs file. The general pattern

is to open a File object, then wrap that in a BufReader. BufReader takes care of providing buffered I/O, which can reduce system calls to the OS if the hard disk is congested.

Listing 2.27 Reading a file manually line by line

```
Creates a File object that
 1 use std::fs::File;
 2 use std::io::BufReader;
                                                                requires a path argument
                                                                and error handling if the file
 3 use std::io::prelude::*;
                                                                does not exist. This program
 4
                                                                crashes if a readme.md is not
 5 fn main() {
                                                                present.
     let f = File::open("readme.md").unwrap();
 7
      let mut reader = BufReader::new(f);
 8
                                                     Reuses a single String
 9
    let mut line = String::new();
                                                     object over the lifetime
                                                     of the program
10
11
     loop {
12
      let len = reader.read line(&mut line)
13
                          .unwrap(); \triangleleft—
                                                    Because reading from disk can fail,
        if len == 0 {
14
                                                    we need to explicitly handle this. In
15
        break
                                                    our case, errors crash the program.
16
17
        println!("{} ({}) ({}) bytes long)", line, len);
18
19
2.0
        line.truncate(0);
                                          Shrinks the String back to length 0,
21
                                          preventing lines from persisting
22 }
                                          into the following ones
```

Manually looping through a file can be cumbersome, despite its usefulness in some cases. For the common case of iterating through lines, Rust provides a helper iterator as the following listing shows. The source code for this listing is in the file ch2/ch2-bufreader-lines.rs.

Listing 2.28 Reading a file line by line via BufReader::lines()

```
1 use std::fs::File;
 2 use std::io::BufReader;
                                                           A subtle behavior change
 3 use std::io::prelude::*;
                                                            occurs here. BufReader::lines()
 4
                                                           removes the trailing newline
 5 fn main() {
                                                           character from each line.
6 let f = File::open("readme.md").unwrap();
 7
    let reader = BufReader::new(f);
                                                               Unwraps the Result, but
 8
                                                               at the risk of crashing the
 9 for line_ in reader.lines() {
                                                               program if an error occurs
     let line = line .unwrap();
1.0
       println!("{} ({} bytes long)", line, line.len());
11
12
13 }
```

We're now in a position to add reading from a file into grep-lite's feature list. The following listing creates a complete program that takes a regular expression pattern and an input file as arguments.

Listing 2.29 Reading lines from a file

```
1 use std::fs::File;
 2 use std::io::BufReader;
 3 use std::io::prelude::*;
 4 use regex::Regex;
 5 use clap::{App,Arg};
 7 fn main() {
   let args = App::new("grep-lite")
9
      .version("0.1")
10
      .about("searches for patterns")
      .arg(Arg::with_name("pattern")
11
        .help("The pattern to search for")
       .takes_value(true)
.required(true))
13
      .arg(Arg::with_name("input")
15
16
       .help("File to search")
17
       .takes_value(true)
18
        .required(true))
19
      .get matches();
20
21
     let pattern = args.value of("pattern").unwrap();
22
     let re = Regex::new(pattern).unwrap();
23
    let input = args.value of("input").unwrap();
24
25
    let f = File::open(input).unwrap();
26
    let reader = BufReader::new(f);
2.7
                                                line is a String, but
28
   for line_ in reader.lines() {
                                                re.find() takes an &str
     let line = line .unwrap();
29
                                                as an argument.
     match re.find(&line) {
30
           Some(_) => println!("{}", line),
31
32
          None \Rightarrow (),
33
34
     }
35 }
```

2.14 Reading from stdin

A command-line utility wouldn't be complete if it wasn't able to read from stdin. Unfortunately for those readers who skimmed over earlier parts of this chapter, some of the syntax on line 8 might look quite unfamiliar. In short, rather than duplicate code within main(), we'll use a generic function to abstract away the details of whether we are dealing with files or stdin:

Listing 2.30 Searching through a file or stdin

```
1 use std::fs::File;
2 use std::io;
3 use std::io::BufReader;
4 use std::io::prelude::*;
5 use regex::Regex;
```

Summary 75

```
6 use clap::{App,Arg};
 8 fn process lines<T: BufRead + Sized>(reader: T, re: Regex) {
    for line in reader.lines() {
10
      let line = line .unwrap();
     match re.find(&line) {
11
                                                 line is a String, but
           Some(_) => println!("{}", line),
12
                                                 re.find() takes an &str
13
           None => (),
                                                as an argument.
14
15
16 }
17
18 fn main() {
19
   let args = App::new("grep-lite")
2.0
     .version("0.1")
21
      .about ("searches for patterns")
      .arg(Arg::with_name("pattern")
2.2
      .help("The pattern to search for")
23
       .takes_value(true)
.required(true))
2.4
25
     .arg(Arg::with name("input")
26
      .help("File to search")
27
28
       .takes value(true)
29
        .required(false))
30
     .get matches();
31
32
     let pattern = args.value of("pattern").unwrap();
     let re = Regex::new(pattern).unwrap();
33
34
35
     let input = args.value of("input").unwrap or("-");
36
37
   if input == "-" {
38
     let stdin = io::stdin();
      let reader = stdin.lock();
39
40
     process lines(reader, re);
41 } else {
42
      let f = File::open(input).unwrap();
     let reader = BufReader::new(f);
43
44
      process lines (reader, re);
45
     }
46 }
```

Summary

- Rust has full support for primitive types, such as integers and floating-point numbers.
- Functions are strongly typed and require types to be specified for their parameters and return values.
- Rust features, such as iteration and mathematical operations, rely on traits. The for loop is a shorthand for the std::iter::IntoIterator trait, for example.
- List-like types are tailored to specific use cases. You will typically reach for Vec<T> first.

- All Rust programs have a single entry function: main().
- Every crate has a Cargo.toml file that specifies its metadata.
- The cargo tool is able to compile your code and fetch its dependencies.
- The rustup tool provides access to multiple compiler toolchains and to the language's documentation.

Compound data types

This chapter covers

- Composing data with structs
- Creating enumerated data types
- Adding methods and handling errors in a typesafe manner
- Defining and implementing common behavior with traits
- Understanding how to keep implementation details private
- Using cargo to build documentation for your project

Welcome to chapter 3. If we spent the last chapter looking at Rust's atoms, this chapter is focused more on its molecules.

This chapter focuses on two key building blocks for Rust programmers, struct and enum. Both are forms of *compound data types*. Together, struct and enum can compose other types to create something more useful than what those other types would be alone. Consider how a 2D point (x,y) is composed from two numbers, x and y. We wouldn't want to maintain two variables, x and y, in our program. Instead,

we would like to refer to the point as a whole entity. In this chapter, we also discuss how to add methods to types with impl blocks. Lastly, we take a deeper look at *traits*, Rust's system for defining interfaces.

Throughout this chapter, you'll work through how to represent files in code. Although conceptually simple—if you're reading this book, it's highly likely you've interacted with a file through code before—there are enough edge cases to make things interesting. Our strategy will be to create a mock version of everything using our own imaginary API. Then, toward the latter part of the chapter, you'll learn how to interact with your actual operating system (OS) and its filesystem(s).

3.1 Using plain functions to experiment with an API

To start, let's see how far we can get by making use of the tools we already know. Listing 3.1 lays out a few things that we would expect, such as opening and closing a file. We'll use a rudimentary mock type to model one: a simple alias around String that holds a filename and little else.

To make things slightly more interesting than writing lots of boilerplate code, listing 3.1 sprinkles in a few new concepts. These show you how to tame the compiler while you're experimenting with your design. It provides attributes (#![allow(unused_variables)]) to relax compiler warnings. The read function illustrates how to define a function that never returns. The code actually doesn't do anything, however. That will come shortly. You'll find the source for this listing in the file ch3/ch3-not-quite-file-1.rs.

Listing 3.1 Using type aliases to stub out a type

```
Relaxes compiler warnings
 1 #![allow(unused variables)]
                                                  while working through ideas
 3 type File = String;
                                                   Creates a type alias. The compiler
                                                  won't distinguish between String &
 5 fn open(f: &mut File) -> bool {
                                                  File, but your source code will.
 6
        true
 7
                                                Let's assume for the moment that
 8 fn close(f: &mut File) -> bool {
                                                these two functions always succeed.
 9
        true
10 }
                                         Relaxes a compiler warning
                                         about an unused function
12 #[allow(dead code)]
13 fn read(f: &mut File,
14
            save to: &mut Vec<u8>) -> ! {
                                                                   The! return type
        unimplemented!()
15
                                                                   indicates to the Rust
                                         A macro that crashes
16 }
                                         the program if it's
                                                                   compiler that this
17
                                         encountered
                                                                   function never returns.
18 fn main() {
        let mut f1 = File::from("f1.txt");
19
                                                            With the type declaration at line 3,
20
        open(&mut f1);
                                                            File inherits all of String's methods.
       //read(f1, vec![]);
22
        close(&mut f1);
                                           There's little point in
23 }
                                           calling this method.
```

There are *lots* of things that needs to be built on from listing 3.1. For example

- We haven't created a persistent object that would represent a file. There's only so much that can be encoded in a string.
- There's no attempt to implement read(). If we did, how would we handle the failure case?
- open() and close() return bool. Perhaps there is a way to provide a more sophisticated result type that might be able to contain an error message if the OS reports one.
- *None of our functions are methods.* From a stylistic point of view, it might be nice to call f.open() rather than open(f).

Let's begin at the top and work our way through this list. Brace yourself for a few scenic detours along the way as we encounter a few side roads that will be profitable to explore.

Special return types in Rust

If you are new to the language, some return types are difficult to interpret. These are also especially difficult to search for because they are made from symbols rather than words.

Known as the *unit type*, () formally is a zero-length tuple. It is used to express that a function returns no value. Functions that appear to have no return type return (), and expressions that are terminated with a semicolon (;) return (). For example, the report () function in the following code block returns the unit type implicitly:

```
use std::fmt::Debug;

fn report<T: Debug>(item: T) {
    println!("{:?}", item);
} 

item can be any type that implements std::fmt::Debug.

**Time can be any type th
```

And this example returns the unit type explicitly:

```
fn clear(text: &mut String) -> () {
   *text = String::from("");
}
Replaces the string at text
with an empty string
}
```

The unit type often occurs in error messages. It's common to forget that the last expression of a function shouldn't end with a semicolon.

The exclamation symbol, !, is known as the "Never" type. Never indicates that a function never returns, especially when it is guaranteed to crash. For example, take this code:

```
fn dead_end() -> ! {
  panic!("you have reached a dead end");
}
The panic! macro causes the
program to crash. This means
the function is guaranteed
never to return.
```

(continued)

The following example creates an infinite loop that prevents the function from returning:

```
fn forever() -> ! {

loop {

//...
};

Unless it contains a break, the loop never finishes. This prevents the function from returning.
```

As with the unit type, Never sometimes occurs within error messages. The Rust compiler complains about mismatched types when you forget to add a break in your loop block if you've indicated that the function returns a non-Never type.

3.2 Modeling files with struct

We need something to represent that thing we're trying to model. struct allows you to create a composite type made up of other types. Depending on your programming heritage, you may be more familiar with terms such as object or record.

We'll start with requiring that our files have a name and zero or more bytes of data. Listing 3.2 prints the following two lines to the console:

```
File { name: "f1.txt", data: [] }
f1.txt is 0 bytes long
```

To represent data, listing 3.2 uses Vec<u8>, which is a growable list of u8 (single byte) values. The bulk of the main() function demonstrates usage (e.g., field access). The file ch3/ch3-mock-file.rs contains the code for this listing.

Listing 3.2 Defining an instance of struct to represent files

```
1 #[derive(Debug)]
                                                    Allows println! to print File. The std::fmt::Debug
                 2 struct File {
                                                    trait works in conjunction with {:?} within the
                 3 name: String,
                                                  macro to enable File as a printable string.
                    data: Vec<u8>,
                 5 }
                                                  Using Vec<u8>, provides access to some useful
 Here the
                                                  conveniences like dynamic sizing, which makes it
vec! macro
                 7 fn main() {
                                                possible to simulate writing to a file
simulates
                 8 let f1 = File {
 an empty
                9 name: String::from("f1.txt"),
                                                                     String::from generates
     file.
               10
                      data: Vec::new(),
                                                                     owned strings from string
                11
                    };
                                                                     literals, which are slices.
                12
                13
                     let f1 name = &f1.name;
                                                                 Accessing fields uses the . operator.
                     let f1 length = &f1.data.len();
                14
                                                                 Accessing fields by reference prevents
                15
                                                                 their use after move issues.
                16 println!("{:?}", f1);
                17
                    println!("{} is {} bytes long", f1 name, f1 length);
                18 }
```

Here is a detailed overview of listing 3.2:

- Lines 1-5 define the File struct. Definitions include fields and their associated types. These also include each field's lifetimes, which happened to be elided here. Explicit lifetimes are required when a field is a reference to another object.
- Lines 8–11 create our first instance of File. We use a literal syntax here, but typically structs in the wild are created via a convenience method. String::from() is one of those convenience methods. It takes a value of another type; in this case, a string slice (&str), which returns a String instance. Vec::new() is the more common case.
- Lines 13–17 demonstrate accessing our new instance's fields. We prepend an ampersand to indicate that we want to access this data by reference. In Rust parlance, this means that the variables fl_name and fl_length are borrowing the data these refer to.

You have probably noticed that our File struct doesn't actually store anything to disk at all. That's actually OK for now. If you're interested, figure 3.1 shows its internals. In the figure, its two fields (name and data) are themselves both created by structs. If you're unfamiliar with the term pointer (ptr), consider pointers to be the same thing as references for now. Pointers are variables that refer to some location in memory. The details are explained at length in chapter 6.

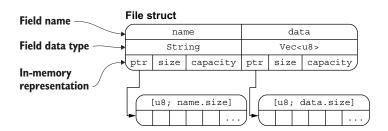

Figure 3.1 Inspecting the internals of the File struct

We'll leave interacting with the hard disk drive or other persistent storage until later in the chapter. For the meantime, let's recreate listing 3.1 and add the File type as promised.

The newtype pattern

Sometimes the type keyword is all that you need. But what about when you need the compiler to treat your new "type" as a fully-fledged, distinct type rather than just an alias? Enter newtype. The newtype pattern consists of wrapping a core type within a single field struct (or perhaps a tuple). The following code shows how to distinguish network hostnames from ordinary strings. You'll find this code in ch3/ch3-newtype-pattern.rs:

```
(continued)
                                    Hostname is
                                    our new type.
                                                     Uses the type system
struct Hostname (String);
                                                     to guard against
                                                    invalid usage
fn connect(host: Hostname) {
 println!("connected to {}", host.0);
                                                   Accesses the underlying
                                                   data with a numeric
fn main() {
    let ordinary string = String::from("localhost");
    let host = Hostname ( ordinary string.clone() );
    connect(ordinary string);
}
Here is the compiler output from rustc:
$ rustc ch3-newtype-pattern.rs
error[E0308]: mismatched types
  --> ch3-newtype-pattern.rs:11:13
        connect(ordinary string);
11
                 expected struct `Hostname`,
                                  found struct `String`
error: aborting due to previous error
For more information about this error, try `rustc --explain E0308`.
Using the newtype pattern can strengthen a program by preventing data from being
silently used in inappropriate contexts. The downside of using the pattern is that each
new type must opt in to all of its intended behavior. This can feel cumbersome.
```

We can now add a little bit of functionality to the first listing of the chapter. Listing 3.3 (available at ch3/ch3-not-quite-file-2.rs) adds the ability to read a file that has some data in it. It demonstrates how to use a struct to mimic a file and simulate reading its contents. It then converts opaque data into a String. All functions are assumed to always succeed, but the code is still littered with hard-coded values. Still, the code finally prints something to the screen. Here is partially obscured output from the program:

```
File { name: "2.txt", data: [114, 117, 115, 116, 33] }
2.txt is 5 bytes long
*****

Revealing this line would
spoil all of the fun!
```

Listing 3.3 Using struct to mimic a file and simulate reading its contents

```
5 name: String,
 6 data: Vec<u8>,
 7 }
 9 fn open(f: &mut File) -> bool {
10 true
                                              These two
11 }
                                              functions remain
                                              inert for now.
12
13 fn close(f: &mut File) -> bool {
14
15 }
                                         Returns the number
16
                                         of bytes read
17 fn read(
18 f: &File,
                                              Makes a copy of the data here
19 save to: &mut Vec<u8>,
                                              because save to.append()
20 ) -> usize {
                                              shrinks the input Vec<T>
21
     let mut tmp = f.data.clone();
22
     let read length = tmp.len();
23
24
     save_to.reserve(read_length);
                                                 Ensures that there is
25
     save to.append(&mut tmp);
                                                sufficient space to fit
26
     read length
                                                the incoming data
27 }
28
                                           Allocates sufficient data in the save to
29 fn main() {
                                          buffer to hold the contents of f
30 let mut f2 = File {
      name: String::from("2.txt"),
32
      data: vec![114, 117, 115, 116, 33],
33
34
     let mut buffer: Vec<u8> = vec![];
35
36
37
     open(&mut f2);
                                                      Does the hard work of
     let f2 length = read(&f2, &mut buffer);
38
                                                      interacting with the file
39
     close(&mut f2);
40
     let text = String::from utf8 lossy(&buffer);
41
                                                                   Converts Vec<u8> to
42
                                                                   String. Any bytes that
     println!("{:?}", f2);
43
                                                                   are not valid UTF-8 are
     println!("{} is {} bytes long", &f2.name, f2 length);
                                                                   replaced with �.
45
     println!("{}", text)
                                      Views the bytes 114, 117, 115,
46 }
                                      116, and 33 as an actual word
47
```

The code so far has tackled two of the four issues raised at the end of listing 3.1:

- Our File struct is a bona fide type.
- read() is implemented, albeit in a memory-inefficient manner.

These last two points remain:

- open() and close() return bool.
- None of our functions are methods.

3.3 Adding methods to a struct with impl

This section explains briefly what methods are and describes how to make use of them in Rust. Methods are functions that are coupled to some object. From a syntactic point of view, these are just functions that don't need to specify one of their arguments. Rather than calling open() and passing a File object in as an argument (read(f, buffer)), methods allow the main object to be implicit in the function call (f.read(buffer)) using the dot operator.¹

Rust is different than other languages that support methods: there is no class keyword. Types created with struct (and enum, which is described later) feel like classes at times, but as they don't support inheritance, it's probably a good thing that they're named something different.

To define methods, Rust programmers use an impl block, which is physically distinct in source code from the struct and enum blocks that you have already encountered. Figure 3.2 shows the differences.

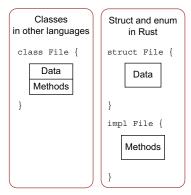

Figure 3.2 Illustrating syntactic differences between Rust and most object oriented languages. Within Rust, methods are defined separately from fields.

3.3.1 Simplifying object creation by implementing new()

Creating objects with reasonable defaults is done through the new() method. Every struct can be instantiated through a literal syntax. This is handy for getting started, but leads to unnecessary verbosity in most code.

Using new() is a convention within the Rust community. Unlike other languages, new is not a keyword and isn't given some sort of blessed status above other methods. Table 3.1 summarizes the conventions.

¹ There are a number of theoretical differences between methods and functions, but a detailed discussion of those computer science topics is available in other books. Briefly, functions are regarded as *pure*, meaning their behavior is determined solely by their arguments. Methods are inherently *impure*, given that one of their arguments is effectively a side effect. These are muddy waters, though. Functions are perfectly capable of acting on side effects themselves. Moreover, methods are implemented with functions. And, to add an exception to an exception, objects sometimes implement *static methods*, which do not include implicit arguments.

Table 3.1 Comparing Rust's literal syntax for creating objects with the use of the new() method

Current usage	With File::new()
<pre>File { name: String::from("f1.txt"), data: Vec::new(), };</pre>	File::new("f1.txt", vec![]);
<pre>File { name: String::from("f2.txt"), data: vec![114, 117, 115, 116, 33], };</pre>	File::new("f2.txt", vec![114, 117, 115, 116, 33]);

To enable these changes, make use of an impl block as the next listing shows (see ch3/ch3-defining-files-neatly.rs). The resulting executable should print out the same message as listing 3.3, substituting f3.txt for the original's f1.txt.

Listing 3.4 Using impl blocks to add methods to a struct

```
1 #[derive(Debug)]
 2 struct File {
 3 name: String,
     data: Vec<u8>,
                                               As File::new() is a completely
 5 }
                                               normal function, we need to
 6
                                               tell Rust that it will return a
 7 impl File {
                                               File from this function.
 8 fn new(name: &str) -> File {
      File {
 9
                                              File::new() does little more than
10
        name: String::from(name),
                                              encapsulate the object creation
                                             syntax, which is normal.
11
         data: Vec::new(),
12
13
14 }
15
                                               Fields are private by default but can
16 fn main() {
                                               be accessed within the module that
17
     let f3 = File::new("f3.txt");
                                               defines the struct. The module system
18
                                         is discussed later in the chapter.
    let f3 name = &f3.name;
19
20
    let f3 length = f3.data.len();
21
     println!("{:?}", f3);
23
     println!("{} is {} bytes long", f3 name, f3 length);
24 }
```

Merging this new knowledge with the example that we already have, listing 3.5 is the result (see ch3/ch3-defining-files-neatly.rs). It prints the following three lines to the console:

Listing 3.5 Using impl to improve the ergonomics of File

```
1 #![allow(unused variables)]
 3 #[derive(Debug)]
 4 struct File {
   name: String,
 6
    data: Vec<u8>,
7 }
9 impl File {
10 fn new(name: &str) -> File {
     File {
       name: String::from(name),
12
13
        data: Vec::new(),
14
     }
15
16
17
    fn new with data(
                                 This method sneaked in to deal with
18
     name: &str,
                                 cases where we want to simulate
19
      data: &Vec<u8>,
                                that a file has pre-existing data.
20
   ) -> File {
21
     let mut f = File::new(name);
22
      f.data = data.clone();
23
      f
24
    }
25
26
   fn read(
27
   self: &File,
                                        Replaces the f
2.8
     save to: &mut Vec<u8>,
                                       argument with self
   ) -> usize {
29
30
    let mut tmp = self.data.clone();
      let read length = tmp.len();
     save to.reserve(read length);
32
33
      save to.append(&mut tmp);
34
       read length
35
36 }
37
38 fn open(f: &mut File) -> bool {
39
     true
40 }
                                            An explicit type needs to be
                                            provided as vec! and can't
42 fn close(f: &mut File) -> bool {
                                            infer the necessary type
   true
                                            through the function
44 }
                                            boundary.
45
46 fn main() {
    let f3 data: Vec<u8> = vec![
      114, 117, 115, 116, 33
48
49
50
    let mut f3 = File::new with data("2.txt", &f3 data);
52
     let mut buffer: Vec<u8> = vec![];
53
```

```
54
     open(&mut f3);
55
     let f3 length = f3.read(&mut buffer);
                                                       Here is the
56
     close(&mut f3);
                                                        change in the
57
                                                        calling code.
     let text = String::from utf8 lossy(&buffer);
58
59
     println!("{:?}", f3);
60
     println!("{} is {} bytes long", &f3.name, f3 length);
61
     println!("{}", text);
63 }
```

3.4 Returning errors

Early on in the chapter, two points were raised discussing dissatisfaction with being unable to properly signify errors:

- *There was no attempt at implementing* read(). If we did, how would we handle the failure case?
- *The methods open() and close() return bool.* Is there a way to provide a more sophisticated result type to contain an error message if the OS reports one?

The issue arises because dealing with hardware is unreliable. Even ignoring hardware faults, the disk might be full or the OS might intervene and tell you that you don't have permission to delete a particular file. This section discusses different methods for signalling that an error has occurred, beginning with approaches common in other languages and finishing with idiomatic Rust.

3.4.1 Modifying a known global variable

One of the simplest methods for signalling that an error has occurred is by checking the value of a global variable. Although notoriously error-prone, this is a common idiom in systems programming.

C programmers are used to checking the value of errno once system calls return. As an example, the close() system call closes a *file descriptor* (an integer representing a file with numbers assigned by the OS) and can modify errno. The section of the POSIX standard discussing the close() system call includes this snippet:

"If close() is interrupted by a signal that is to be caught, it shall return -1 with errno set to EINTR and the state of fildes [file descriptor] is unspecified. If an I/O error occurred while reading from or writing to the file system during close(), it may return -1 with errno set to EIO; if this error is returned, the state of fildes is unspecified."

```
—The Open Group Base Specifications (2018)
```

Setting errno to either EIO or EINTR means to set it to some magical internal constant. The specific values are arbitrary and defined per OS. With the Rust syntax, checking global variables for error codes would look something like the following listing.

Listing 3.6 Rust-like code that checks error codes from a global variable

```
static mut ERROR: i32 = 0;
                                                       A global variable, static mut (or
                                                        mutable static), with a static lifetime
              // ...
                                                        that's valid for the life of the program
              fn main() {
                let mut f = File::new("something.txt");
                read(f, buffer);
                unsafe {
                                                                                           Accessing and
               → if ERROR != 0 {
     Checks
                                                                                           modifying static
                     panic!("An error has occurred while reading the file ")
 the ERROR
                                                                                           mut variables
value. Error
                                                                                           requires the use of
                }
   checking
                                                                                            an unsafe block.
relies on the
                                                                                            This is Rust's way
                                                                                            of disclaiming all
 convention
                close(f);
                                                                                           responsibility.
that 0 means
                unsafe {
   no error.
               → if ERROR != 0 {
                     panic! ("An error has occurred while closing the file ")
                }
              }
```

Listing 3.7, presented next, introduces some new syntax. The most significant is probably the unsafe keyword, whose significance we'll discuss later in the book. In the meantime, consider unsafe to be a warning sign rather than an indicator that you're embarking on anything illegal. Unsafe means "the same level of safety offered by C at all times." There are also some other small additions to the Rust language that you know already:

- Mutable global variables are denoted with static mut.
- By convention, global variables use ALL CAPS.
- A const keyword is included for values that never change.

Figure 3.3 provides a visual overview of the flow control error and error handling in listing 3.7.

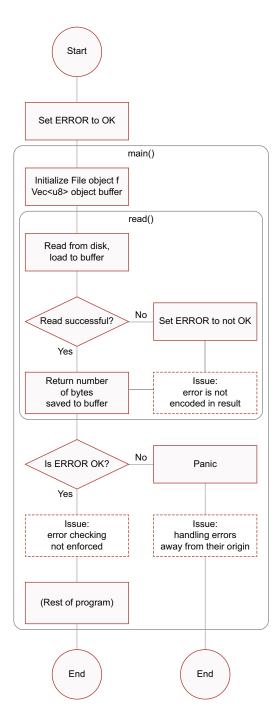

Figure 3.3 A visual overview of listing 3.7, including explanations of problems with using global error codes

Listing 3.7 Using global variables to propagate error information

```
1 use rand::{random};
                                                   Brings the rand crate
                                                 into local scope
 3 static mut ERROR: isize = 0;
                                             Initializes ERROR to 0
 5 struct File; <───
                                       Creates a zero-sized type to stand in for
                                      a struct while we're experimenting
 7 #[allow(unused variables)]
 8 fn read(f: &File, save to: &mut Vec<u8>) -> usize {
      if random() && random() && random() {
                                                                 Returns true one out
10
        unsafe {
                                   Sets ERROR to 1, notifying the rest of the system that
                                                                 of eight times this
11
           ERROR = 1;  < ---
                                                                function is called
                                   an error has occurred
13
14
                 Always reads 0 bytes
15 }
16
17 #[allow(unused_mut)]
                                     Keeping buffer mutable for
18 fn main() {
                                    consistency with other code though it isn't touched here
                                      consistency with other code even
19 let mut f = File;
2.0
      let mut buffer = vec![];
21
                                     Accessing static mut variables is
22 read(&f, &mut buffer);
                                     an unsafe operation.
2.3
     unsafe {
2.4
       if ERROR != 0 {
2.5
               panic!("An error has occurred!")
26
       }
27
28 }
```

Here are the commands that you will need to use to experiment with the project at listing 3.7:

- 1 git clone --depth=1 https://github.com/rust-in-action/code rust-inaction to download the book's source code
- 2 cd rust-in-action/ch3/globalerror to move into the project directory
- 3 cargo run to execute the code

If you prefer to do things manually, there are more steps to follow:

- 1 cargo new --vcs none globalerror to create a new blank project.
- 2 cd globalerror to move into the project directory.
- 3 cargo add rand@0.8 to add version 0.8 of the rand crate as a dependency (run cargo install cargo-edit if you receive an error message that cargo add command is unavailable).
- 4 As an optional step, you can verify that the rand crate is now a dependency by inspecting Cargo.toml at the root of the project. It will contain the following two lines:

```
[dependencies]
rand = "0.8"
```

- 5 Replace the contents of src/main.rs with the code in listing 3.7 (see ch3/globalerror/src/main.rs).
- 6 Now that your source code is in place, execute cargo run.

You should see output like this:

\$ cargo run

```
Compiling globalerror v0.1.0 (file:///path/to/globalerror)
 *Finished* dev [unoptimized + debuginfo] target(s) in 0.74 secs
 *Running* `target/debug/globalerror`
```

Most of the time, the program will not do anything. Occasionally, if the book has enough readers with sufficient motivation, it will print a much louder message:

\$ cargo run

Experienced programmers will know that using the global variable errno is commonly adjusted by the OS during system calls. This style of programming would typically be discouraged in Rust because it omits both type safety (errors are encoded as plain integers) and can reward sloppy programmers with unstable programs when they forget to check the errno value. However, it's an important style to be aware of because

- Systems programmers may need to interact with OS-defined global values.
- Software that interacts with CPU registers and other low-level hardware needs to get used to inspecting flags to check that operations were completed successfully.

The difference between const and let

If variables defined with let are immutable, then why does Rust include a const keyword? The short answer is that data behind let *can* change. Rust allows types to have an apparently contradictory property of *interior mutability*.

Some types such as std:sync::Arc and std:rc::Rc present an immutable façade, yet change their internal state over time. In the case of those two types, these increment a reference count as references to those are made and decrement that count when those references expire.

At the level of the compiler, let relates more to aliasing than immutability. *Aliasing* in compiler terminology refers to having multiple references to the same location in memory at the same time. Read-only references (borrows) to variables declared with let can alias the same data. Read-write references (mutable borrows) are guaranteed to never alias data.

3.4.2 Making use of the Result return type

Rust's approach to error handling is to use a type that stands for both the standard case and the error case. This type is known as Result. Result has two states, Ok and Err. This two-headed type is versatile and is put to work all through the standard library.

We'll consider *how* a single type can act as two later on. For the moment, let's investigate the mechanics of working with it. Listing 3.8 makes changes from previous iterations:

- Functions that interact with the file system, such as open() on line 39, return Result<File, String>. This effectively allows two types to be returned. When the function successfully executes, File is returned within a wrapper as Ok (File). When the function encounters an error, it returns a String within its own wrapper as Err(String). Using a String as an error type provides an easy way to report error messages.
- Calling functions that return Result<File, String> requires an extra method (unwrap()) to actually extract the value. The unwrap() call unwraps Ok(File) to produce File. It will crash the program if it encounters Err(String). More sophisticated error handling is explained in chapter 4.
- open() and close() now take full ownership of their File arguments. While we'll defer a full explanation of the term ownership until chapter 4, it deserves a short explanation here.

Rust's ownership rules dictate when values are deleted. Passing the File argument to open() or close() without prepending an ampersand, e.g. &File or &mut File, passes ownership to the function that is being called. This would ordinarily mean that the argument is deleted when the function ends, but these two also return their arguments at the end.

■ The f4 variable now needs to reclaim ownership. Associated with the changes to the open() and close() functions is a change to the number of times that let f4 is used. f4 is now rebound after each call to open() and close(). Without this, we would run into issues with using data that is no longer valid.

To run the code in listing 3.8, execute these commands from a terminal window:

```
$ git clone --depth=1 https://github.com/rust-in-action/code rust-in-action
$ cd rust-in-action/ch3/fileresult
$ cargo run
```

To do things by hand, here are the recommended steps:

- Move to a scratch directory, such as /tmp; for example, cd \$TMP (cd \$TMP\$ on MS Windows).
- 2 Execute cargo new --bin --vcs none fileresult.
- 3 Ensure that the crate's Cargo.toml file specifies the 2018 edition and includes the rand crate as a dependency:

```
[package]
name = "fileresult"
version = "0.1.0"
authors = ["Tim McNamara <author@rustinaction.com>"]
edition = "2018"

[dependencies]
rand = "0.8"
```

- 4 Replace the contents of fileresult/src/main.rs with the code in listing 3.8 (ch3/fileresult/src/main.rs).
- 5 Execute cargo run.

Executing cargo run produces debugging output, but nothing from the executable itself:

\$ cargo run

```
Compiling fileresult v0.1.0 (file:///path/to/fileresult)
Finished dev [unoptimized + debuginfo] target(s) in 1.04 secs
Running `target/debug/fileresult`
```

Listing 3.8 Using Result to mark functions liable to filesystem errors

```
1 use rand::prelude::*;
                                                              Brings common traits and
                                                              types from the rand crate
 3 fn one in(denominator: u32) -> bool {
                                                   <1
                                                              into this crate's scope
     thread rng().gen ratio(1, denominator)
 5 }
                                                           Helper function
                                   thread rng() creates a
                                                           that triggers
 7 #[derive(Debug)]
                            thread-local random number
                                                           sporadic errors
 8 struct File {
                             generator; gen_ratio(n, m)
 9 name: String,
                            returns a Boolean value with
    data: Vec<u8>,
10
                                      an n/m probability.
11 }
12
13 impl File {
14 fn new(name: &str) -> File {
15 File {
        name: String::from(name),
       data: Vec::new()
17
18
                             Stylistic change to
     }
19
                            shorten the code block
20
     fn new with data(name: &str, data: &Vec<u8>) -> File {
2.1
      let mut f = File::new(name);
       f.data = data.clone();
23
24
25
26
                                               First appearance of Result<T, E>,
27 fn read(
                                               where T is an integer of type usize
2.8
     self: &File,
                                               and E is a String. Using String
      save_to: &mut Vec<u8>,
29
                                               provides arbitrary error messages.
30
    ) -> Result<usize, String> {
```

```
let mut tmp = self.data.clone();
      let read length = tmp.len();
     save_to.reserve(read_length);
save_to.append(&mut tmp);

we still wrap read_length in Ok because we're returning Result.
                                         In this code, read() never fails, but
34
35
     Ok(read length)
36
37 }
                                                       Once in 10,000
38
                                                       executions,
39 fn open(f: File) -> Result<File, String> {
                                                      returns an error
40 if one in(10 000) {
      let err msg = String::from("Permission denied");
42
      return Err(err msq);
43
44
    Ok(f)
45 }
46
47 fn close(f: File) -> Result<File, String> {
48 if one_in(100 000) {
                                                                    Once in 100,000
     let err msg = String::from("Interrupted by signal!");
                                                                    executions.
50
      return Err(err msg);
                                                                    returns an error
51 }
52
    Ok(f)
53 }
54
55 fn main() {
    let f4_data: Vec<u8> = vec![114, 117, 115, 116, 33];
    let mut f4 = File::new with data("4.txt", &f4 data);
58
59
    let mut buffer: Vec<u8> = vec![];
    f4 = open(f4).unwrap();
                                                            Unwraps T from
    let f4_length = f4.read(&mut buffer).unwrap();
62
                                                            Ok, leaving T
63
    f4 = close(f4).unwrap();
67
65
    let text = String::from utf8 lossy(&buffer);
66
    println!("{:?}", f4);
67
    println!("{} is {} bytes long", &f4.name, f4 length);
    println!("{}", text);
70 }
```

NOTE Calling .unwrap() on a Result is often considered poor style. When called on an error type, the program crashes without a helpful error message. As the chapter progresses, we'll encounter sophisticated mechanisms to handle errors.

Using Result provides compiler-assisted code correctness: your code won't compile unless you've taken the time to handle the edge cases. This program will fail on error, but at least we have made this explicit.

So, what is a Result? Result is an enum defined in Rust's standard library. It has the same status as any other type but is tied together with the rest of the language through strong community conventions. You may be wondering, "Wait. What is an enum?" I'm glad you asked. That's the topic of our next section.

3.5 Defining and making use of an enum

An *enum*, or enumeration, is a type that can represent multiple known variants. Classically, an enum represents several predefined known options like the suits of playing cards or planets in the solar system. The following listing shows one such enum.

Listing 3.9 Defining an enum to represent the suits in a deck of cards

```
enum Suit {
  Clubs,
  Spades,
  Diamonds,
  Hearts,
}
```

If you haven't programmed in a language that makes use of enums, understanding their value takes some effort. As you program with these for a while, though, you're likely to experience a minor epiphany.

Consider creating some code that parses event logs. Each event has a name, perhaps UPDATE or DELETE. Rather than storing those values as strings in your application, which can lead to subtle bugs later on when string comparisons become unwieldy, enums allow you to give the compiler some knowledge of the event codes. Later, you'll be given a warning such as "Hi there, I see that you have considered the UPDATE case, but it looks like you've forgotten the DELETE case. You should fix that."

Listing 3.10 shows the beginnings of an application that parses text and emits structured data. When run, the program produces the following output. You'll find the code for this listing in ch3/ch3-parse-log.rs:

```
(Unknown, "BEGIN Transaction XK342")
(Update, "234:LS/32231 {\"price\": 31.00} -> {\"price\": 40.00}")
(Delete, "342:LO/22111")
```

Listing 3.10 Defining an enum and using it to parse an event log

```
Prints this enum to the screen
                 1 #[derive(Debug)]
                                                    via auto-generated code
                 2 enum Event {
                    Update,
                 3
                                     Creates three variants of
                       Delete,
                                     Event, including a value
                                     for unrecognized events
                 5
                       Unknown,
                                                                                     A function for
                 6 }
                                                                                     parsing a line and
 Vec< >
                7
                                                   A convenient name for String
                                                                                     converting it into
 asks Rust
                                                                                     semi-structured
to infer the
                9
                                                                                     data
 elements'
                10 fn parse log(line: &str) -> (Event, Message) {
    type.
            → 11 let parts: Vec< > = line
                                                                   collect() consumes an iterator from
                                            .splitn(2, ' ')
                                                               line.splitn() and returns Vec<T>.
                                            .collect();
                13
                    if parts.len() == 1 {
                                                                                   If line.splitn() doesn't
                15
                     return (Event::Unknown, String::from(line))
                                                                                   split log into two parts,
                16
                                                                                  returns an error
```

```
17
18 let event = parts[0];
                                        Assigns each part of parts to a
19 let rest = String::from(parts[1]); variable to ease future use
2.0
21 match event {
     "UPDATE" | "update" => (Event::Update, rest),
                                                   When we match a known event,
     "DELETE" | "delete" => (Event::Delete, rest), | returns structured data
If we don't recognize
                                                       the event type, returns
26 }
                                                       the whole line
2.7
28 fn main() {
29 let log = "BEGIN Transaction XK342
30 UPDATE 234:LS/32231 {\"price\": 31.00} -> {\"price\": 40.00}
31 DELETE 342:LO/22111";
33 for line in log.lines() {
let parse_result = parse_log(line);
     println!("{:?}", parse result);
36 }
37 }
```

Enums have a few tricks up their sleeves:

- These work together with Rust's pattern-matching capabilities to help you build robust, readable code (visible on lines 19–3 of listing 3.10).
- Like structs, enums support methods via impl blocks.
- Rust's enums are more powerful than a set of constants.

It's possible to include data within an enum's variants, granting them a struct-like persona. For example

```
enum Suit {
    Clubs,
    Spades,
    Diamonds,
    Hearts,
}

enum Card {
    King(Suit),
    Queen(Suit),
    Jack(Suit),
    Ace(Suit),
    Pip(Suit, usize),
}
```

3.5.1 Using an enum to manage internal state

Now that you've seen how to define and use an enum, how is this useful when applied to modelling files? We can expand our File type and allow it to change as it is opened and closed. Listing 3.11 (ch3/ch3-file-states.rs) produces code that prints a short alert to the console:

```
Error checking is working
File { name: "5.txt", data: [], state: Closed }
5.txt is 0 bytes long
```

Listing 3.11 An enum that represents a File being open or closed

```
1 #[derive(Debug, PartialEq)]
 2 enum FileState {
 3 Open,
    Closed,
 5 }
 6
 7 #[derive(Debug)]
8 struct File {
9 name: String,
10 data: Vec<u8>,
11 state: FileState,
12 }
13
14 impl File {
15 fn new(name: &str) -> File {
     File {
16
17
      name: String::from(name),
       data: Vec::new(),
18
19
       state: FileState::Closed,
     }
20
21
    }
22
23 fn read(
     self: &File,
24
25
     save_to: &mut Vec<u8>,
26 ) -> Result<usize, String> {
27
     if self.state != FileState::Open {
28
       return Err(String::from("File must be open for reading"));
29
     let mut tmp = self.data.clone();
3.0
31
     let read_length = tmp.len();
32
     save to.reserve(read length);
33
     save to.append(&mut tmp);
34
      Ok (read length)
35
   }
36 }
37
38 fn open(mut f: File) -> Result<File, String> {
39 f.state = FileState::Open;
40
    Ok(f)
41 }
43 fn close(mut f: File) -> Result<File, String> {
44 f.state = FileState::Closed;
    Ok(f)
45
46 }
47
48 fn main() {
49  let mut f5 = File::new("5.txt");
```

```
50
51
    let mut buffer: Vec<u8> = vec![];
52
53
   if f5.read(&mut buffer).is err() {
54
     println!("Error checking is working");
55
56
57
   f5 = open(f5).unwrap();
5.8
    let f5 length = f5.read(&mut buffer).unwrap();
    f5 = close(f5).unwrap();
59
60
61
    let text = String::from utf8 lossy(&buffer);
62
    println!("{:?}", f5);
64 println!("{} is {} bytes long", &f5.name, f5 length);
65 println!("{}", text);
66 }
```

Enums can be a powerful aide in your quest to produce reliable, robust software. Consider them for your code when you discover yourself introducing "stringly-typed" data, such as message codes.

3.6 Defining common behavior with traits

A robust definition of the term *file* needs to be agnostic to storage medium. Files support two main operations: reading and writing streams of bytes. Focusing on those two capabilities allows us to ignore where the reads and writes are actually taking place. These actions can be from a hard disk drive, an in-memory cache, over a network, or via something more exotic.

Irrespective of whether a file is a network connection, a spinning metal platter, or a superposition of an electron, it's possible to define rules that say, "To call yourself a file, you must implement this."

You have already seen traits in action several times. Traits have close relatives in other languages. These are often named interfaces, protocols, type classes, abstract base classes, or, perhaps, contracts.

Every time you've used #[derive(Debug)] in a type definition, you've implemented the Debug trait for that type. Traits permeate the Rust language. Let's see how to create one.

3.6.1 Creating a Read trait

Traits enable the compiler (and other humans) to know that multiple types are attempting to perform the same task. Types that use #[derive(Debug)] all print to the console via the println! macro and its relatives. Allowing multiple types to implement a Read trait enables code reuse and allows the Rust compiler to perform its zero cost abstraction wizardry.

For the sake of brevity, listing 3.12 (ch3/ch3-skeleton-read-trait.rs) is a bare-bones version of the code that we've already seen. It shows the distinction between the trait keyword, which is used for definitions, and the impl keyword, which attaches a trait to

a specific type. When built with rustc and executed, listing 3.12 prints the following line to the console:

0 byte(s) read from File

Listing 3.12 Defining the bare bones of a Read trait for File

```
1 #![allow(unused_variables)]
                                           Silences any warnings relating to
                                            unused variables within functions
 3 # [derive (Debug)]
 4 struct File;
                           Defines a stub File type
 6 trait Read {
                           Provides a specific
 7 fn read(
                          name for the trait
 8
       self: &Self,
                                                   A trait block includes the type
        save to: &mut Vec<u8>,
 9
                                                   signatures of functions that
    ) -> Result<usize, String>;
                                                   implementors must comply with. The
10
                                                   pseudo-type Self is a placeholder for the
11 }
                                                   type that eventually implements Read.
12
13 impl Read for File {
       fn read(self: &File, save to: &mut Vec<u8>) -> Result<usize, String> {
14
15
                            A simple stub value that
16
                            complies with the type
17 }
                            signature required
18
19 fn main() {
20 let f = File{};
21
       let mut buffer = vec!();
22
      let n bytes = f.read(&mut buffer).unwrap();
       println!("{} byte(s) read from {:?}", n bytes, f);
23
24 }
```

Defining a trait and implementing it on the same page can feel quite drawn out in small examples such as this. File is spread across three code blocks within listing 3.12. The flip side of this is that many common traits become second nature as your experience grows. Once you've learned what the PartialEq trait does for one type, you'll understand it for every other type.

What does PartialEq do for types? It enables comparisons with the == operator. "Partial" allows for cases where two values that match exactly should not be treated as equal, such as the floating point's NAN value or SQL's NULL.

NOTE If you've spent some time looking through the Rust community's forums and documentation, you might have noticed that they've formed their own idioms of English grammar. When you see a sentence with the following structure, "...T is Debug...", what they're saying is that T implements the Debug trait.

3.6.2 Implementing std::fmt::Display for your own types

The println! macro and a number of others live within a family of macros that all use the same underlying machinery. The macros println!, print!, write!, writeln!, and format! all rely on the Display and Debug traits, and these rely on trait implementations provided by programmers to convert from {} to what is printed to the console.

Looking back a few pages to listing 3.11, the File type was composed of a few fields and a custom subtype, FileState. If you recall, that listing illustrated the use of the Debug trait as repeated in the following listing.

Listing 3.13 Snippets from listing 3.11

```
#[derive(Debug, PartialEq)]
            enum FileState {
               Open,
               Closed,
            #[derive(Debug)]
            struct File {
              name: String,
              data: Vec<u8>,
               state: FileState,
         → //...
            fn main() {
  Lines
              let f5 = File::new("f5.txt");
skipped
from the
original
                                                 Debug relies on the
                                          colon and question
             println!("{:?}", f5);
                                               mark syntax.
             // ...
```

It's possible to rely on the Debug trait auto-implementations as a crutch, but what should you do if you want to provide custom text? Display requires that types implement a fmt method, which returns fmt::Result. The following listing shows this implementation.

Listing 3.14 Using std::fmt::Display for File and its associated FileState

```
impl Display for FileState {
 fn fmt(&self, f:
        &mut fmt::Formatter,
 ) -> fmt::Result {
                        <
-
   match *self {
     FileState::Open => write!(f, "OPEN"),
     FileState::Closed => write!(f, "CLOSED"),
                                                   To implement
                                                   std::fmt::Display, a
                                                   single fmt method
                                                   must be defined for
                                                  your type.
impl Display for File {
  fn fmt(&self, f:
         &mut fmt::Formatter,
   write!(f, "<{} ({})>",
```

```
self.name, self.state)
}

It is common to defer to the inner types' Display implementation via the write! macro.
```

The following listing shows how to implement Display for a struct that includes fields that also need to implement Display. You'll find the code for this listing in ch3/ch3-implementing-display.rs.

Listing 3.15 Working code snippet to implement Display

```
1 #![allow(dead code)]
                                                Silences warnings related to
 2
                                                FileState::Open not being used
 3 use std::fmt;
 4 use std::fmt::{Display};
                                            Brings the std::fmt crate into local
                                            scope, making use of fmt::Result
 6 #[derive(Debug, PartialEq)]
 7 enum FileState {
                                         Brings Display into local scope,
   Open,
                                         avoiding the need to prefix it as
 9
     Closed,
                                         fmt::Display
10 }
11
12 #[derive(Debug)]
13 struct File {
14 name: String,
15
    data: Vec<u8>,
16
     state: FileState,
17 }
18
19 impl Display for FileState {
20 fn fmt(&self, f: &mut fmt::Formatter) -> fmt::Result {
21
       match *self {
22
            FileState::Open => write!(f, "OPEN"),
                                                                  Sneakily, we can make use
                                                                  of write! to do the grunt
23
             FileState::Closed => write!(f, "CLOSED"),
                                                                  work for us. Strings
24
                                                                  already implement
25
      }
                                                                  Display, so there's little
26 }
                                                                  left for us to do.
27
28 impl Display for File {
    fn fmt(&self, f: &mut fmt::Formatter) -> fmt::Result {
         write!(f, "<{} ({})>",
30
31
            self.name, self.state)
                                                 We can rely on this
32
                                                 FileState Display
33 }
                                                 implementation.
34
35 impl File {
36 fn new(name: &str) -> File {
37
       File {
38
            name: String::from(name),
           data: Vec::new(),
39
40
            state: FileState::Closed,
41
42
43 }
```

```
44
45 fn main() {
46  let f6 = File::new("f6.txt");
47  //...
48  println!("{:?}", f6);
49  println!("{}", f6);
50 }

The Debug implementation prints a familiar message in common with all other implementors of Debug: File { ... }.

Our Display implementation follows its own rules, displaying itself as <f6.txt (CLOSED)>.
```

We'll see many uses of traits throughout the course of the book. These underlie Rust's generics system and the language's robust type checking. With a little bit of abuse, these also support a form of inheritance that's common in most object oriented languages. For now, though, the thing to remember is that traits represent common behavior that types opt into via the syntax impl Trait for Type.

3.7 Exposing your types to the world

Your crates will interact with others that you build over time. You might want to make that process easier for your future self by hiding internal details and documenting what's public. This section describes some of the tooling available within the language and within cargo to make that process easier.

3.7.1 Protecting private data

Rust defaults to keeping things private. If you were to create a library with only the code that you have seen so far, importing your crate would provide no extra benefit. To remedy this, use the pub keyword to make things public.

Listing 3.16 provides a few examples of prefixing types and methods with pub. As you'll note, its output is not very exciting:

```
File { name: "f7.txt", data: [], state: Closed }
```

Listing 3.16 Using pub to mark the name and state fields of File public

```
1 # [derive (Debug, PartialEg)]
 2 pub enum FileState {
                                    An enum's variants are
     Open,
                                     assumed to be public if the
 4
    Closed,
                                    overall type is made public.
 5 }
 7 #[derive(Debug)]
                                File.data remains private if
 8 pub struct File {
                                  a third party were to import
 9 pub name: String,
                                  this crate via use.
10 data: Vec<u8>,
    pub state: FileState,
11
                                                    Even though the File struct
12 }
                                                    is public, its methods must
13
                                                    also be explicitly marked
14 impl File {
                                                    as public.
pub fn new(name: &str) -> File {
16
     File {
           name: String::from(name),
```

3.8 Creating inline documentation for your projects

When software systems become larger, it becomes more important to document one's progress. This section walks through adding documentation to your code and generating HTML versions of that content.

In listing 3.17, you'll see the familiar code with some added lines beginning with /// or //!. The first form is much more common. It generates documents that refer to the item that immediately follows. The second form refers to the current item as the compiler scans the code. By convention, it is only used to annotate the current module but is available in other places as well. The code for this listing is in the file ch3-file-doced.rs.

Listing 3.17 Adding doc comments to code

```
1 //! Simulating files one step at a time.
                                                          //! refers to the current
                                                          item, the module that's
 3 /// Represents a "file",
                                                          just been entered by the
 4 /// which probably lives on a file system.
                                                         compiler.
 5 #[derive(Debug)]
 6 pub struct File {
                                                        /// annotates whatever
 7
    name: String,
                                                        immediately follows it.
    data: Vec<u8>,
 9 }
10
11 impl File {
    /// New files are assumed to be empty, but a name is required.
   pub fn new(name: &str) -> File {
13
        name: String::from(name),
15
         data: Vec::new(),
16
17
     }
18
19
     /// Returns the file's length in bytes.
20
     pub fn len(&self) -> usize {
2.1
22
     self.data.len()
23
24
25
     /// Returns the file's name.
     pub fn name(&self) -> String {
```

3.8.1 Using rustdoc to render docs for a single source file

You may not know it, but you also installed a command-line tool called rustdoc when you installed Rust. rustdoc is like a special-purpose Rust compiler. Instead of producing executable code, it produces HTML versions of your inline documentation.

Here is how to use it. Assuming that you have the code from listing 3.17 saved as ch3-file-doced.rs, follow these steps:

- 1 Open a terminal.
- 2 Move to the location of your source file.
- 3 Execute rustdoc ch3-file-doced.rs.

rustdoc creates a directory (doc/) for you. The documentation's entry point is actually within a subdirectory: doc/ch3_file_doced/index.html.

When your programs start to get larger and span multiple files, invoking rustdoc manually can become a bit of a pain. Thankfully, cargo can do the grunt work on your behalf. That's discussed in the next section.

3.8.2 Using cargo to render docs for a crate and its dependencies

Your documentation can be rendered as rich HTML output with cargo. cargo works with crates rather than the individual files as we've worked with so far. To get around this, we'll move our project into a crate documentation: To manually create the crate, following these instructions:

- 1 Open a terminal.
- 2 Move to a working directory, such as /tmp/, or for Windows, type cd %TEMP%.
- 3 Run cargo new filebasics.

You should end up with a project directory tree that looks like this:

```
filebasics

—Cargo.toml
—src
—main.rs

—main.rs

—This file is what you'll edit in the following steps.
```

4 Now save the source code from listing 3.17 to filebasics/src/main.rs, overwriting the "Hello World!" boilerplate code that is already in the file.

To skip a few steps, clone the repository. Execute these commands from a terminal:

```
$ git clone https://github.com/rust-in-action/code rust-in-action
$ cd rust-in-action/ch3/filebasics
```

To build an HTML version of the crate's documentation, follow these steps:

- Move to the project's root directory (filebasics/), which includes the Cargo .toml file.
- 2 Run cargo doc --open.

Rust will now starts to compile an HTML version of your code's documentation. You should see output similar to the following in the console:

```
Documenting filebasics v0.1.0 (file:///C:/.../Temp/filebasics)

Finished dev [unoptimized + debuginfo] target(s) in 1.68 secs

Opening C:\...\Temp\files\target\doc\filebasics\index.html

Launching cmd /C
```

If you added the --open flag, your web browser will automatically. Figure 3.4 shows the documentation that should now be visible.

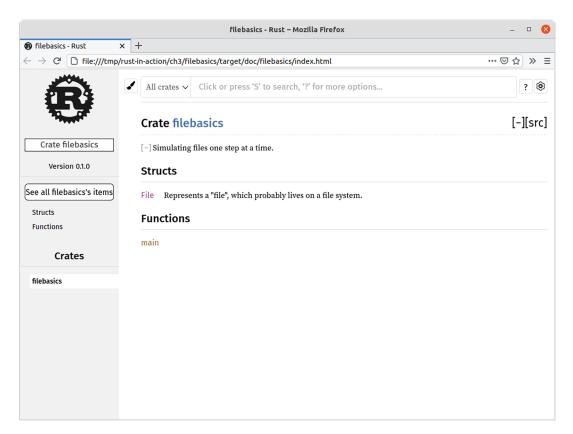

Figure 3.4 Rendered output of cargo doc

TIP If you have lots of dependencies in your crate, the build process may take a while. A useful flag is cargo doc --no-deps. Adding --no-deps can significantly restrict the work rustdoc has to do.

rustdoc supports rendering rich text written in Markdown. That allows you to add headings, lists, and links within your documentation. Code snippets that are wrapped in triple backticks (```) are given syntax highlighting.

Listing 3.18 Documenting Rust code with in-line comments

```
1 //! Simulating files one step at a time.

```

Summary

- A struct is the foundational compound data type. Paired with traits, structs are the closest thing to objects from other domains.
- An enum is more powerful than a simple list. Enum's strength lies in its ability to work with the compiler to consider all edge cases.
- Methods are added to types via impl blocks.
- You can use global error codes in Rust, but this can be cumbersome and generally is frowned on.
- The Result type is the mechanism the Rust community prefers to use to signal the possibility of error.
- Traits enable common behavior through Rust programs.
- Data and methods remain private until they are declared public with pub.
- You can use cargo to build the documentation for your crate and all of its dependencies.

Lifetimes, ownership, and borrowing

This chapter covers

- Discovering what the term lifetime means in Rust programming
- Working with the borrow checker rather than against it
- Multiple tactics for dealing with issues when these crop up
- Understanding the responsibilities of an owner
- Learning how to borrow values that are owned elsewhere

This chapter explains one of the concepts that trip up most newcomers to Rust—its borrow checker. The *borrow checker* checks that all access to data is legal, which allows Rust to prevent safety issues. Learning how this works will, at the very least, speed up your development time by helping you avoid run-ins with the compiler. More significantly though, learning to work with the borrow checker allows you to build larger software systems with confidence. It underpins the term *fearless concurrency*.

This chapter will explain how this system operates and help you learn how to comply with it when an error is discovered. It uses the somewhat lofty example of simulating a satellite constellation to explain the trade-offs relating to different ways to provide shared access to data. The details of borrow checking are thoroughly explored within the chapter. However, a few points might be useful for readers wanting to quickly get the gist. Borrow checking relies on three interrelated concepts—lifetimes, ownership, and borrowing:

- Ownership is a stretched metaphor. There is no relationship to property rights. Within Rust, ownership relates to cleaning values when these are no longer needed. For example, when a function returns, the memory holding its local variables needs to be freed. Owners cannot prevent other parts of the program from accessing their values or report data theft to some overarching Rust authority.
- A value's lifetime is the period when accessing that value is valid behavior. A function's local variables live until the function returns, while global variables might live for the life of the program.
- To borrow a value means to access it. This terminology is somewhat confusing as there is no obligation to return the value to its owner. Its meaning is used to emphasize that while values can have a single owner, it's possible for many parts of the program to share access to those values.

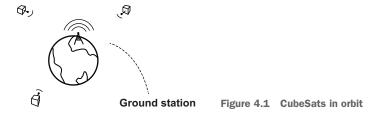

4.1 Implementing a mock CubeSat ground station

Our strategy for this chapter is to use an example that compiles. Then we'll make a minor change that triggers an error that appears to emerge without any adjustment to the program's flow. Working through the fixes to those issues should make the concepts more complete.

The learning example for the chapter is a CubeSat constellation. If you've never encountered that phrase before, here are some definitions:

- *CubeSat*—A miniature artificial satellite, as compared to a conventional satellite, that has increasingly expanded the accessibility of space research.
- *Ground station*—An intermediary between the operators and the satellites themselves. It listens on a radio, checking the status of every satellite in the constellation and transmitting messages to and fro. When introduced in our code, it acts as the gateway between the user and the satellites.
- *Constellation*—The collective noun for satellites in orbit.

Figure 4.1 shows several CubeSats orbiting our ground station.

In figure 4.1, we have three CubeSats. To model this, we'll create a variable for each. This model can happily implement integers for the moment. We don't need to model the ground station explicitly because we're not yet sending messages around the constellations. We'll omit that model for now. These are the variables:

```
let sat_a = 0;
let sat_b = 1;
let sat c = 2;
```

To check on the status of each of our satellites, we'll use a stub function and an enum to represent potential status messages:

The check_status() function would be extremely complicated in a production system. For our purposes, though, returning the same value every time is perfectly sufficient. Pulling these two snippets into a whole program that "checks" our satellites twice, we end up with something like the following listing. You'll find this code in the file ch4/ch4-check-sats-1.rs.

Listing 4.1 Checking the status of our integer-based CubeSats

```
1 #![allow(unused variables)]
 3 #[derive(Debug)]
 4 enum StatusMessage {
 5 Ok,
 6 }
 8 fn check status(sat id: u64) -> StatusMessage {
   StatusMessage::Ok
9
10 }
11
12 fn main () {
13 let sat a = 0;
                       Each satellite variable
14
    let sat b = 1;
                        is represented by an
15  let sat_c = 2;
                       integer.
16
17
     let a status = check status(sat a);
18
    let b_status = check_status(sat_b);
19
    let c status = check status(sat c);
    println!("a: {:?}, b: {:?}, c: {:?}", a_status, b_status, c_status);
20
21
    // "waiting" ...
22
23 let a status = check status(sat a);
```

```
24 let b_status = check_status(sat_b);
25 let c_status = check_status(sat_c);
26 println!("a: {:?}, b: {:?}, c: {:?}", a_status, b_status, c_status);
27 }
```

Running the code in listing 4.1 should be fairly uneventful. The code compiles, albeit begrudgingly. We encounter the following output from our program:

```
a: Ok, b: Ok, c: Ok
a: Ok, b: Ok, c: Ok
```

4.1.1 Encountering our first lifetime issue

Let's move closer to idiomatic Rust by introducing *type safety*. Instead of integers, let's create a type to model our satellites. A real implementation of a CubeSat type would probably include lots of information about its position, its RF frequency band, and more. In the following listing, we stick with only recording an identifier.

Listing 4.2 Modeling a CubeSat as its own type

```
#[derive(Debug)]
struct CubeSat {
  id: u64,
}
```

Now that we have a struct definition, let's inject it into our code. The next listing will not compile (yet). Understanding the details of why it won't is the goal of much of this chapter. The source for this listing is in ch4/ch4-check-sats-2.rs.

Listing 4.3 Checking the status of our integer-based CubeSats

```
1 #[derive(Debug)]
                              Modification 1
 2 struct CubeSat {
                              adds the
   id: u64,
                             definition.
 4 }
 6 #[derive(Debug)]
 7 enum StatusMessage {
   Ok,
9 }
10
                                 Modification 2 uses
11 fn check status(
                                 the new type within
12 sat id: CubeSat
                                check_status().
13 ) -> StatusMessage {
14 StatusMessage::Ok
15 }
16
17 fn main() {
18  let sat a = CubeSat { id: 0 };
                                          Modification 3
19  let sat b = CubeSat { id: 1 };
                                           creates three
                                          new instances.
20  let sat c = CubeSat { id: 2 };
21
```

```
let a_status = check_status(sat_a);
let b_status = check_status(sat_b);
let c_status = check_status(sat_c);
println!("a: {:?}, b: {:?}, c: {:?}", a_status, b_status, c_status);

// "waiting" ...
let a_status = check_status(sat_a);
let b_status = check_status(sat_b);
let c_status = check_status(sat_c);
println!("a: {:?}, b: {:?}, c: {:?}", a_status, b_status, c_status);
}
```

When you attempt to compile the code for listing 4.3, you will receive a message similar to the following (which has been edited for brevity):

To trained eyes, the compiler's message is helpful. It tells us exactly where the problem is and provides us with a recommendation on how to fix it. To less experienced eyes, it's significantly less useful. We are using a "moved" value and are fully advised to implement the Copy trait on CubeSat. Huh? It turns out that although it is written in English, the term *move* means something very specific within Rust. Nothing physically moves.

Movement within Rust code refers to movement of ownership, rather than the movement of data. *Ownership* is a term used within the Rust community to refer to the compile-time process that checks that every use of a value is valid and that every value is destroyed cleanly.

Every value in Rust is *owned*. In both listings 4.1 and 4.3, sat_a, sat_b, and sat_c own the data that these refer to. When calls to check_status() are made, ownership of the data moves from the variables in the scope of main() to the variable sat_id within the check_status() function. The significant difference is that listing 4.3 places that integer within a CubeSat struct.¹ This type change alters the semantics of how the program behaves.

¹ Remember the phrase *zero-cost abstractions*? One of the ways this manifests is by not adding extra data around values within structs.

The next listing provides a stripped-down version of the main() function from listing 4.3. It is centered on sat_a and attempts to show how ownership moves from main() into check status().

Listing 4.4 Extract of listing 4.3, focusing on main()

```
fn main() {
                                                               Ownership originates
                let sat a = CubeSat { id: 0 };
                                                              here at the creation of
                                                               the CubeSat object.
            ⊳ // ...
               let a status = check status(sat a);
                                                                      Ownership of the object
    Lines
                                                                      moves to check status() but
  skipped
                                                                     is not returned to main().
for brevity
               // "waiting" ...
               let a status = check status(sat a);
                                                                      At line 27, sat a is no longer
            → // ...
                                                                      the owner of the object,
                                                                      making access invalid.
```

Rebinding is legal when values are not borrowed

If you have experience with programming languages such as JavaScript (from 2015 onward), you may have been surprised to see that the variables for each of the CubeSats were redefined in listing 4.3. In that listing on line 20, a_status is assigned to the result of the first call to <code>check_status(sat_a)</code>. On line 26, it is reassigned to the result of the second call. The original value is overwritten.

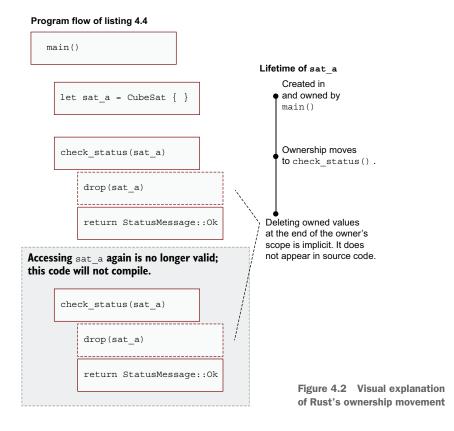

This is legal Rust code, but one must be aware of ownership issues and lifetime here too. It's possible in this context because there are no live borrows to contend with. Attempting to overwrite a value that's still available from elsewhere in the program causes the compiler to refuse to compile your program.

Figure 4.2 provides a visual walk-through of the interrelated processes of control flow, ownership, and lifetimes. During the call to check_status(sat_a), ownership moves to the check_status() function. When check_status() returns a StatusMessage, it drops the sat_a value. The lifetime of sat_a ends here. Yet, sat_a remains in the local scope of main() after the first call to check_status(). Attempting to access that variable will incur the wrath of the borrow checker.

The distinction between a value's lifetime and its scope—which is what many programmers are trained to rely on—can make things difficult to disentangle. Avoiding and overcoming this type of issue makes up the bulk of this chapter. Figure 4.2 helps to shed some light on this.

4.1.2 Special behavior of primitive types

Before carrying on, it might be wise to explain why listing 4.1 compiled at all. Indeed, the only change that we made in listing 4.3 was to wrap our satellite variables in a custom type. As it happens, primitive types in Rust have special behavior. These implement the Copy trait.

Types implementing Copy are duplicated at times that would otherwise be illegal. This provides some day-to-day convenience at the expense of adding a trap for newcomers. As you grow out from toy programs using integers, your code suddenly breaks.

Formally, primitive types are said to possess *copy semantics*, whereas all other types have *move semantics*. Unfortunately, for learners of Rust, that special case looks like the default case because beginners typically encounter primitive types first. Listings 4.5 and 4.6 illustrate the difference between these two concepts. The first compiles and runs; the other does not. The only difference is that these listings use different types. The following listing shows not only the primitive types but also the types that implement Copy.

Listing 4.5 The copy semantics of Rust's primitive types

```
1 fn use_value(_val: i32) {
2 }
3
4 fn main() {
5 let a = 123;
6 use_value(a);
use_value() takes ownership
of the _val argument. The
use_value() function is
generic as it's used in
the next example.
```

```
8 println!("{}", a);
9 It's perfectly legal to access a after use_value() has returned.
```

The following listing focuses on those types that do not implement the Copy trait. When used as an argument to a function that takes ownership, values cannot be accessed again from the outer scope.

Listing 4.6 The move semantics of types not implementing Copy

```
1 fn use value ( val: Demo) {
                                              use value() takes
                                              ownership of val.
 3
 4 struct Demo {
     a: i32,
 7
 8 fn main() {
     let demo = Demo { a: 123 };
                                           It's illegal to access
    use value(demo);
10
                                           demo.a, even after
11
                                           use_value() has returned.
     println!("{}", demo.a);
13 }
```

4.2 Guide to the figures in this chapter

The figures used in this chapter use a bespoke notation to illustrate the three interrelated concepts of scope, lifetimes, and ownership. Figure 4.3 illustrates this notation.

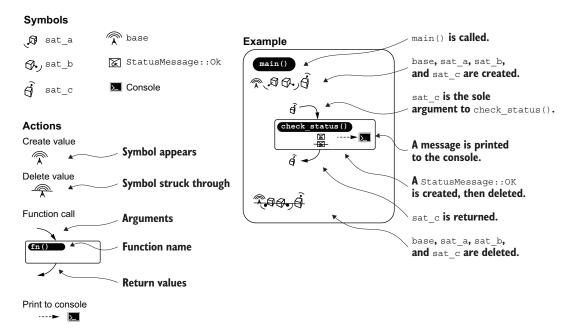

Figure 4.3 How to interpret the figures in this chapter

4.3 What is an owner? Does it have any responsibilities?

In the world of Rust, the notion of *ownership* is rather limited. An owner cleans up when its values' lifetimes end.

When values go out of scope or their lifetimes end for some other reason, their destructors are called. A *destructor* is a function that removes traces of the value from the program by deleting references and freeing memory. You won't find a call to any destructors in most Rust code. The compiler injects that code itself as part of the process of tracking every value's lifetime.

To provide a custom destructor for a type, we implement Drop. This typically is needed in cases where we have used unsafe blocks to allocate memory. Drop has one method, drop (&mut self), that you can use to conduct any necessary wind-up activities.

An implication of this system is that values cannot outlive their owner. This kind of situation can make data structures built with references, such as trees and graphs, feel slightly bureaucratic. If the root node of a tree is the owner of the whole tree, it can't be removed without taking ownership into account.

Finally, unlike the Lockean notion of personal property, ownership does not imply control or sovereignty. In fact, the "owners" of values do not have special access to their owned data. Nor do these have the ability to restrict others from trespassing. Owners don't get a say on other sections of code borrowing their values.

4.4 How ownership moves

There are two ways to shift ownership from one variable to another within a Rust program. The first is by assignment.² The second is by passing data through a function barrier, either as an argument or a return value. Revisiting our original code from listing 4.3, we can see that sat_a starts its life with ownership over a CubeSat object:

```
fn main() {
  let sat_a = CubeSat { id: 0 };
  // ...
```

The CubeSat object is then passed into check_status() as an argument. This moves ownership to the local variable sat id:

```
fn main() {
  let sat_a = CubeSat { id: 0 };
  // ...
  let a_status = check_status(sat_a);
  // ...
```

Another possibility is that sat_a relinquishes its ownership to another variable within main(). That would look something like this:

² Within the Rust community, the term *variable binding* is preferred because it is more technically correct.

```
fn main() {
  let sat_a = CubeSat { id: 0 };
  // ...
  let new_sat_a = sat_a;
  // ...
```

Lastly, if there is a change in the <code>check_status()</code> function signature, it too could pass ownership of the <code>CubeSat</code> to a variable within the calling scope. Here is our original function:

```
fn check_status(sat_id: CubeSat) -> StatusMessage {
   StatusMessage::Ok
}
```

And here is an adjusted function that achieves its message notification through a side effect:

With the adjusted <code>check_status()</code> function used in conjunction with a new <code>main()</code>, it's possible to send ownership of the <code>CubeSat</code> objects back to their original variables. The following listing shows the code. Its source is found in <code>ch4/ch4-check-sats-3.rs</code>.

Listing 4.7 Returning ownership back to the original scope

```
1 #![allow(unused variables)]
 3 # [derive (Debug)]
 4 struct CubeSat {
   id: u64,
 6 }
7
8 #[derive(Debug)]
9 enum StatusMessage {
10 Ok,
11 }
12
13 fn check status(sat id: CubeSat) -> CubeSat {
14 println!("{:?}: {:?}", sat id, StatusMessage::Ok);
15
   sat id
16 }
17
18 fn main () {
19 let sat a = CubeSat { id: 0 };
20  let sat b = CubeSat { id: 1 };
21  let sat_c = CubeSat { id: 2 };
```

```
22
23
     let sat_a = check_status(sat_a);
                                                     Now that the return value
24
     let sat b = check status(sat b);
                                                     of check status() is the
     let sat c = check status(sat c);
25
                                                     original sat a, the new
26
                                                     let binding is reset.
27
     // "waiting" ...
2.8
29
     let sat_a = check_status(sat_a);
30
     let sat b = check status(sat b);
     let sat c = check status(sat c);
31
32 }
```

The output from the new main() function in listing 4.7 now looks like this:

```
CubeSat { id: 0 }: 0k
CubeSat { id: 1 }: 0k
CubeSat { id: 2 }: 0k
CubeSat { id: 0 }: 0k
CubeSat { id: 1 }: 0k
CubeSat { id: 1 }: 0k
CubeSat { id: 2 }: 0k
```

Figure 4.4 shows a visual overview of the ownership movements within listing 4.7.

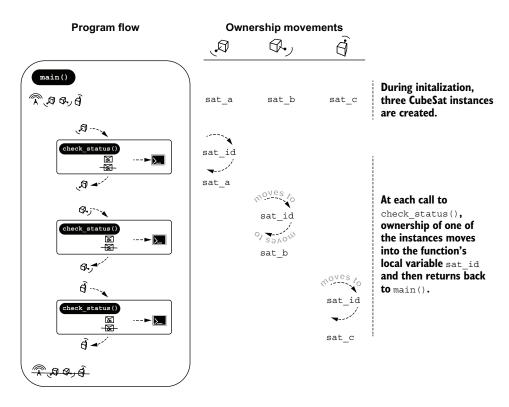

Figure 4.4 The ownership changes within listing 4.7

4.5 Resolving ownership issues

Rust's ownership system is excellent. It provides a route to memory safety without needing a garbage collector. There is a "but," however.

The ownership system can trip you up if you don't understand what's happening. This is particularly the case when you bring the programming style from your past experience to a new paradigm. Four general strategies can help with ownership issues:

- Use references where full ownership is not required.
- Duplicate the value.
- Refactor code to reduce the number of long-lived objects.
- Wrap your data in a type designed to assist with movement issues.

To examine each of these strategies, let's extend the capabilities of our satellite network. Let's give the ground station and our satellites the ability to send and receive messages. Figure 4.5 shows what we want to achieve: create a message at Step 1, then transfer it at Step 2. After Step 2, no ownership issues should arise.

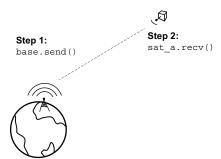

Figure 4.5 Goal: Enable messages to be sent while avoiding ownership issues

Ignoring the details of implementing the methods, we want to avoid code that looks like the following. Moving ownership of sat_a to a local variable in base.send() ends up hurting us. That value will no longer be accessible for the rest of main():

```
base.send(sat_a, "hello!"); 
sat_a.recv();

Moves ownership of sat_a to a local variable in base.send()
```

To get to a "toy" implementation, we need a few more types to help us out somewhat. In listing 4.8, we add a new field, mailbox, to CubeSat. CubeSat.mailbox is a Mailbox struct that contains a vector of Messages within its messages field. We alias String to Message, giving us the functionality of the String type without needing to implement it ourselves.

Listing 4.8 Adding a Mailbox type to our system

```
1 #[derive(Debug)]
2 struct CubeSat {
3  id: u64,
```

```
4 mailbox: Mailbox,
5 }
6
7 #[derive(Debug)]
8 enum StatusMessage {
9 Ok,
10 }
11
12 #[derive(Debug)]
13 struct Mailbox {
14 messages: Vec<Message>,
15 }
16
17 type Message = String;
```

Creating a CubeSat instance has become slightly more complicated. To create one now, we also need to create its associated Mailbox and the mailbox's associated Vec<Message>. The following listing shows this addition.

Listing 4.9 Creating a new CubeSat with Mailbox

```
CubeSat { id: 100, mailbox: Mailbox { messages: vec![] } }
```

Another type to add is one that represents the ground station itself. We will use a bare struct for the moment, as shown in the following listing. That allows us to add methods to it and gives us the option of adding a mailbox as a field later on as well.

Listing 4.10 Defining a struct to represent our ground station

```
struct GroundStation;
```

Creating an instance of GroundStation should be trivial for you now. The following listing shows this implementation.

Listing 4.11 Creating a new ground station

```
GroundStation {};
```

Now that we have our new types in place, let's put these to work. You'll see how in the next section.

4.5.1 Use references where full ownership is not required

The most common change you will make to your code is to reduce the level of access you require. Instead of requesting ownership, you can use a "borrow" in your function definitions. For read-only access, use & T. For read-write access, use &mut T.

Ownership might be needed in advanced cases, such as when functions want to adjust the lifetime of their arguments. Table 4.1 compares the two different approaches.

Table 4.1 Comparing ownership and mutable references

Using ownership	Using a mutable reference
<pre>fn send(to: CubeSat, msg: Message) { to.mailbox.messages.push(msg); }</pre>	<pre>fn send(to: &mut CubeSat, msg: Message) { to.mailbox.messages.push(msg); }</pre>
Ownership of the to variable moves into $\mbox{send}()$. When $\mbox{send}()$ returns, to is deleted.	Adding the &mut prefix to the CubeSat type allows the outer scope to retain ownership of data referred to by the to variable.

Sending messages will eventually be wrapped up in a method, but with essence functions, implementing that modifies the internal mailbox of the CubeSat. For simplicity's sake, we'll return () and hope for the best in case of transmission difficulties caused by solar winds.

The following snippet shows the flow that we want to end up with. The ground station can send a message to sat_a with its send() method, and sat_a then receives the message with its recv() method:

```
base.send(sat_a, "hello!".to_string());
let msg = sat_a.recv();
println!("sat_a received: {:?}", msg); // -> Option("hello!")
```

The next listing shows the implementations of these methods. To achieve that flow, add the implementations to GroundStation and CubeSat types.

Listing 4.12 Adding the GroundStation.send() and CubeSat.recv() methods

```
1 impl GroundStation {
 2 fn send(
                                   &self indicates that GroundStation.send() only requires
 3
        &self,
                                   a read-only reference to self. The recipient takes a
         to: &mut CubeSat,
                                   mutable borrow (&mut) of the CubeSat instance, and
 5
        msg: Message,
                                msg takes full ownership of its Message instance.
       ) {
 7
            to.mailbox.messages.push(msg);
                                                           Ownership of the Message
 8
                                                           instance transfers from
 9 }
                                                           msg to messages.push()
10
                                                           as a local variable.
11 impl CubeSat {
        fn recv(&mut self) -> Option<Message> {
13
            self.mailbox.messages.pop()
14
15 }
```

Notice that both GroundStation.send() and CubeSat.recv() require mutable access to a CubeSat instance because both methods modify the underlying CubeSat.messages vector. We move ownership of the message that we're sending into the messages.push(). This provides us with some quality assurance later, notifying us if we access a message after it's already sent. Figure 4.6 illustrates how we can avoid ownership issues.

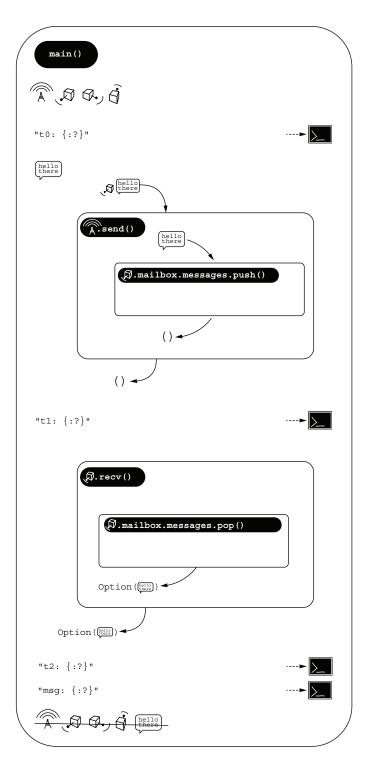

Figure 4.6 Game plan: Use references to avoid ownership issues.

Listing 4.13 (ch4/ch4-sat-mailbox.rs) brings together all of the code snippets in this section thus far and prints the following output. The messages starting with t0 through t2 are added to assist your understanding of how data is flowing through the program:

```
t0: CubeSat { id: 0, mailbox: Mailbox { messages: [] } }
t1: CubeSat { id: 0, mailbox: Mailbox { messages: ["hello there!"] } }
t2: CubeSat { id: 0, mailbox: Mailbox { messages: [] } }
msq: Some("hello there!")
```

Listing 4.13 Avoiding ownership issues with references

```
1 #[derive(Debug)]
 2 struct CubeSat {
   id: u64,
 4
    mailbox: Mailbox,
 5 }
 7 #[derive(Debug)]
8 struct Mailbox {
9 messages: Vec<Message>,
10 }
11
12 type Message = String;
13
14 struct GroundStation;
15
16 impl GroundStation {
fn send(&self, to: &mut CubeSat, msg: Message) {
18
           to.mailbox.messages.push(msg);
19
20 }
21
22 impl CubeSat {
23 fn recv(&mut self) -> Option<Message> {
           self.mailbox.messages.pop()
2.4
25
26 }
27
28 fn main() {
29  let base = GroundStation {};
      let mut sat a = CubeSat {
3.0
31
        id: 0,
32
       mailbox: Mailbox {
         messages: vec![],
                                                             We don't have a
        },
34
                                                             completely ergonomic
35
       };
                                                             way to create Message
                                                             instances yet. Instead,
36
     println!("t0: {:?}", sat_a);
                                                             we'll take advantage of
37
                                                             the String.from() method
3.8
                                                             that converts &str to
39
       base.send(&mut sat a,
                                                            String (aka Message).
                 Message::from("hello there!"));
40
```

```
41
42     println!("t1: {:?}", sat_a);
43
44     let msg = sat_a.recv();
45     println!("t2: {:?}", sat_a);
46
47     println!("msg: {:?}", msg);
48 }
```

4.5.2 Use fewer long-lived values

If we have a large, long-standing object such as a global variable, it can be somewhat unwieldy to keep this around for every component of your program that needs it. Rather than using an approach involving long-standing objects, consider making objects that are more discrete and ephemeral. Ownership issues can sometimes be resolved by considering the design of the overall program.

In our CubeSat case, we don't need to handle much complexity at all. Each of our four variables—base, sat_a, sat_b, and sat_c—live for the duration of main(). In a production system, there can be hundreds of different components and many thousands of interactions to manage. To increase the manageability of this kind of scenario, let's break things apart. Figure 4.7 presents the game plan for this section.

To implement this kind of strategy, we will create a function that returns CubeSat identifiers. That function is assumed to be a black box that's responsible for communicating with some store of identifiers, such as a database. When we need to communicate with a satellite, we'll create a new object, as the following code snippet shows. In this way, there is no requirement for us to maintain live objects for the whole of the program's duration. It also has the dual benefit that we can afford to transfer ownership of our short-lived variables to other functions:

```
fn fetch_sat_ids() -> Vec<u64> {
    vec![1,2,3]
}
Returns a vector
of CubeSat IDs
```

We'll also create a method for GroundStation. This method allows us to create a CubeSat instance on demand once:

```
impl GroundStation {
  fn connect(&self, sat_id: u64) -> CubeSat {
    CubeSat { id: sat_id, mailbox: Mailbox { messages: vec![] } }
}
```

Now we are a bit closer to our intended outcome. Our main function looks like the following code snippet. In effect, we've implemented the first half of figure 4.7.

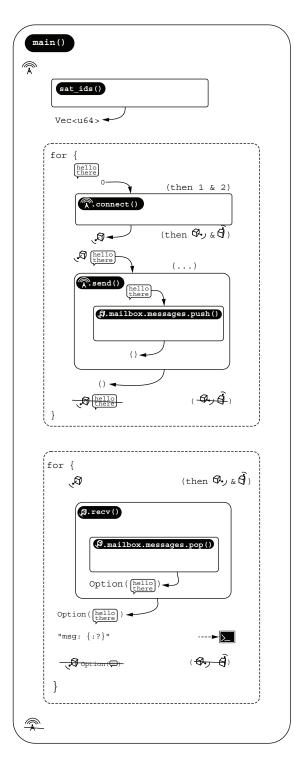

Figure 4.7 Game plan: Short-lived variables to avoid ownership issues

```
fn main() {
  let base = GroundStation();

  let sat_ids = fetch_sat_ids();

  for sat_id in sat_ids {
    let mut sat = base.connect(sat_id);

    base.send(&mut sat, Message::from("hello"));
  }
}
```

But there's a problem. Our CubeSat instances die at the end of the for loop's scope, along with any messages that base sends to them. To carry on with our design decision of short-lived variables, the messages need to live somewhere outside of the CubeSat instances. In a real system, these would live on the RAM of a device in zero gravity. In our not-really-a-simulator, let's put these in a buffer object that lives for the duration of our program.

Our message store will be a Vec<Message> (our Mailbox type defined in one of the first code examples of this chapter). We'll change the Message struct to add a sender and recipient field, as the following code shows. That way our now-proxy CubeSat instances can match their IDs to receive messages:

```
#[derive(Debug)]
struct Mailbox {
  messages: Vec<Message>,
}
#[derive(Debug)]
struct Message {
    to: u64,
    content: String,
}
```

We also need to reimplement sending and receiving messages. Up until now, CubeSat objects have had access to their own mailbox object. The central GroundStation also had the ability to sneak into those mailboxes to send messages. That needs to change now because only one mutable borrow can exist per object.

In the modifications in listing 4.14, the Mailbox instance is given the ability to modify its own message vector. When any of the satellites transmit messages, these take a mutable borrow to the mailbox. These then defer the delivery to the mailbox object. According to this API, although our satellites are able to call Mailbox methods, these are not allowed to touch any internal Mailbox data themselves.

Listing 4.14 Modifications to Mailbox

```
1 impl GroundStation {
2    fn send(
3    &self,
```

```
mailbox: &mut Mailbox,
 5
          to: &CubeSat,
          msg: Message,
 7
                                            Calls Mailbox.post() to
 8
            mailbox.post(to, msg);
                                           send messages, yielding
 9
                                           ownership of a Message
10 }
11
12 impl CubeSat {
13
      fn recv(
                                             Calls Mailbox.deliver() to
14
        &self,
                                             receive messages, gaining
15
        mailbox: &mut Mailbox
                                             ownership of a Message
16
       ) -> Option<Message> {
17
            mailbox.deliver(&self)
18
                                                           Mailbox.post() requires
19 }
                                                           mutable access to itself
20
                                                           and ownership over a
21 impl Mailbox {
                                                           Message.
        fn post(&mut self, msg: Message) {
23
            self.messages.push(msg);
24
25
26
      fn deliver(
                                                   Mailbox.deliver() requires a
27
        &mut self,
                                                   shared reference to a CubeSat
        recipient: &CubeSat
2.8
                                                   to pull out its id field.
29
       ) -> Option<Message> {
30
            for i in 0..self.messages.len() {
                 if self.messages[i].to == recipient.id {
31
32
                      let msg = self.messages.remove(i);
33
                     return Some (msg);
                                                           When we find a message,
34
                                                           returns early with the
            }
35
                                                           Message wrapped in Some
36
                                                           per the Option type
37
            None
                            When no messages are
38
                            found, returns None
39 }
```

NOTE Astute readers of listing 4.14 will notice a strong anti-pattern. On line 32, the self.messages collection is modified while it is being iterated over. In this instance, this is legal because of the return on the next line. The compiler can prove that another iteration will not occur and allows the mutation to proceed.

With that groundwork in place, we're now able to fully implement the strategy laid out in figure 4.7. Listing 4.15 (ch4/ch4-short-lived-strategy.rs) is the full implementation of the short-lived variables game plan. The output from a compiled version of that listing follows:

```
CubeSat { id: 1 }: Some(Message { to: 1, content: "hello" })
CubeSat { id: 2 }: Some(Message { to: 2, content: "hello" })
CubeSat { id: 3 }: Some(Message { to: 3, content: "hello" })
```

Listing 4.15 Implementing the short-lived variables strategy

```
1 #![allow(unused_variables)]
 3 #[derive(Debug)]
 4 struct CubeSat {
     id: u64,
 6 }
 8 #[derive(Debug)]
 9 struct Mailbox {
10 messages: Vec<Message>,
11 }
12
13 #[derive(Debug)]

    let mut mail = Mailbox { messages: vec![] };
61
63
    let base = GroundStation {};
64
65
    let sat ids = fetch sat ids();
66
67
    for sat_id in sat_ids {
     let sat = base.connect(sat id);
     let msg = Message { to: sat id, content: String::from("hello") };
69
70
     base.send(&mut mail, msg);
71
72
73
    let sat_ids = fetch_sat_ids();
74
75
    for sat id in sat ids {
76
     let sat = base.connect(sat id);
77
78
     let msg = sat.recv(&mut mail);
79
      println!("{:?}: {:?}", sat, msg);
80
81 }
```

4.5.3 Duplicate the value

Having a single owner for every object can mean significant up-front planning and/or refactoring of your software. As we saw in the previous section, it can be quite a lot of work to wriggle out of an early design decision.

One alternative to refactoring is to simply copy values. Doing this often is typically frowned upon, however, but it can be useful in a pinch. Primitive types like integers are a good example of that. Primitive types are cheap for a CPU to duplicate—so cheap, in fact, that Rust always copies these if it would otherwise worry about ownership being moved.

Types can opt into two modes of duplication: cloning and copying. Each mode is provided by a trait. Cloning is defined by std::clone::Clone, and the copying mode is defined by std::marker::Copy. Copy acts implicitly. Whenever ownership would otherwise be moved to an inner scope, the value is duplicated instead. (The bits of object a are replicated to create object b.) Clone acts explicitly. Types that implement Clone have a .clone() method that is permitted to do whatever it needs to do to create a new value. Table 4.2 outlines the major differences between the two modes.

Table 4.2 Distinguishing cloning from copying

Cloning (std::clone::Clone)	Copying (std::marker::Copy)
 May be slow and expensive. Never implicit. A call to the .clone() method is always required. May differ from original. Crate authors define what cloning means for their types. 	 Always fast and cheap. Always implicit. Always identical. Copies are bit-for-bit duplicates of the original value.

So why do Rust programmers not always use Copy? There are three main reasons:

- *The Copy trait implies that there will only be negligible performance impact.* This is true for numbers but not true for types that are arbitrarily large, such as String.
- Because Copy creates exact copies, it cannot treat references correctly. Naïvely copying a reference to T would (attempt to) create a second owner of T. That would cause problems later on because there would be multiple attempts to delete T as each reference is deleted.
- Some types overload the Clone trait. This is done to provide something similar to, yet different from, creating duplicates. For example, std::rc::Rc<T> uses Clone to create additional references when .clone() is called.

NOTE Throughout your time with Rust, you will normally see the std::clone ::Clone and std::marker::Copy traits referred to simply as Clone and Copy. These are included in every crate's scope via the standard prelude.

IMPLEMENTING COPY

Let's go back to our original example (listing 4.3), which caused the original movement issue. Here it is replicated for convenience, with sat b and sat c removed for brevity:

```
#[derive(Debug)]
struct CubeSat {
   id: u64,
}

#[derive(Debug)]
enum StatusMessage {
   Ok,
}

fn check_status(sat_id: CubeSat) -> StatusMessage {
   StatusMessage::Ok
}

fn main() {
   let sat_a = CubeSat { id: 0 };
   let a_status = check_status(sat_a);
   println!("a: {:?}", a_status);
```

```
let a_status = check_status(sat_a);
println!("a: {:?}", a_status);
}
The second call to check_status(sat_a)
is the location of error.
```

At this early stage, our program consisted of types that contain types, which themselves implement Copy. That's good because it means implementing it ourselves is fairly straightforward, as the following listing shows.

Listing 4.16 Deriving Copy for types made up of types that implement Copy

```
#[derive(Copy,Clone,Debug)]
struct CubeSat {
   id: u64,
}

#[derive(Copy,Clone,Debug)]
tells the compiler to add an implementation of each of the traits.

#[derive(Copy,Clone,Debug)]
enum StatusMessage {
   Ok,
}
```

The following listing shows how it's possible to implement Copy manually. The impl blocks are impressively terse.

Listing 4.17 Implementing the Copy trait manually

```
impl Copy for CubeSat { }
                                       Implementing Copy
impl Copy for StatusMessage { }
                                       requires an implementation
                                       of Clone.
impl Clone for CubeSat {
  fn clone(&self) -> Self {
    CubeSat { id: self.id }
                                         If desired, we can write out
                                         the creation of a new object
}
                                         ourselves...
impl Clone for StatusMessage {
  fn clone(&self) -> Self {
    *self
                             ...but often we can simply
                             dereference self.
}
```

USING CLONE AND COPY

Now that we know how to implement them, let's put Clone and Copy to work. We've discussed that Copy is implicit. When ownership would otherwise move, such as during assignment and passing through function barriers, data is copied instead.

Clone requires an explicit call to .clone(). That's a useful marker in non-trivial cases, such as in listing 4.18, because it warns the programmer that the process may be expensive. You'll find the source for this listing in ch4/ch4-check-sats-clone-and-copytraits.rs.

Listing 4.18 Using Clone and Copy

```
1 #[derive(Debug, Clone, Copy)]
 2 struct CubeSat {
                                         Copy implies
     id: u64,
                                         Clone, so we
 4 }
                                         can use either
                                         trait later.
 6 #[derive(Debug, Clone, Copy)]
 7 enum StatusMessage {
     Ok,
 9 }
10
11 fn check status(sat id: CubeSat) -> StatusMessage {
     StatusMessage::Ok
13 }
14
15 fn main () {
16
     let sat a = CubeSat { id: 0 };
17
     let a_status = check_status(sat_a.clone());
18
                                                          Cloning each object is as
19
     println!("a: {:?}", a status.clone());
                                                          easy as calling .clone().
20
21
     let a status = check status(sat a);
                                               Copy works
22
     println!("a: {:?}", a status);
                                               as expected.
23 }
```

4.5.4 Wrap data within specialty types

So far in this chapter, we have discussed Rust's ownership system and ways to navigate the constraints it imposes. A final strategy that is quite common is to use *wrapper* types, which allow more flexibility than what is available by default. These, however, incur costs at runtime to ensure that Rust's safety guarantees are maintained. Another way to phrase this is that Rust allows programmers to opt in to garbage collection.³

To explain the wrapper type strategy, let's introduce a wrapper type: std:rc::Rc. std:rc::Rc takes a type parameter T and is typically referred to as Rc<T>. Rc<T> reads as "R. C. of T" and stands for "a reference-counted value of type T." Rc<T> provides *shared ownership* of T. Shared ownership prevents T from being removed from memory until every owner is removed.

As indicated by the name, *reference counting* is used to track valid references. As each reference is created, an internal counter increases by one. When a reference is dropped, the count decreases by one. When the count hits zero, T is also dropped.

Wrapping T involves a calling Rc::new(). The following listing, at ch4/ch4-rc-groundstation.rs, shows this approach.

³ Garbage collection (often abbreviated as GC) is a strategy for memory management used by many programming languages, including Python and JavaScript, and all languages built on the JVM (Java, Scala, Kotlin) or the CLR (C#, F#).

Listing 4.19 Wrapping a user-defined type in Rc

```
1 use std::rc::Rc;
                                   The use keyword brings
                                   modules from the standard
 3 #[derive(Debug)]
                                   library into local scope.
 4 struct GroundStation {}
                                                               Wrapping involves enclosing
                                                               the GroundStation instance
 6 fn main() {
                                                              in a call to Rc::new().
    let base = Rc::new(GroundStation {});
     println!("{:?}", base);
 9
                                          Prints
10 }
                                          "GroundStation"
```

Rc<T> implements Clone. Every call to base.clone() increments an internal counter. Every Drop decrements that counter. When the internal counter reaches zero, the original instance is freed.

Rc<T> does not allow mutation. To permit that, we need to wrap our wrapper. Rc<RefCell<T>> is a type that can be used to perform interior mutability, first introduced at the end of of chapter 3 in section 3.4.1. An object that has interior mutability presents an immutable façade while internal values are being modified.

In the following example, we can modify the variable base despite being marked as an immutable variable. It's possible to visualize this by looking at the changes to the internal base.radio freq:

```
base: RefCell { value: GroundStation { radio_freq: 87.65 } }
base_2: GroundStation { radio_freq: 75.31 }
base: RefCell { value: GroundStation { radio_freq: 75.31 } }
base: RefCell { value: "<borrowed>" }
base_3: GroundStation { radio_freq: 118.52000000000001 }

value: "<borrowed>"
indicates that base is
mutably borrowed
somewhere else and
is no longer generally
accessible.
```

The following listing, found at ch4/ch4-rc-refcell-groundstation.rs, uses Rc<RefCell<T>> to permit mutation within an object marked as immutable. Rc<RefCell<T>> incurs some additional runtime cost over Rc<T> while allowing shared read/write access to T.

Listing 4.20 Using Rc<RefCell<T>> to mutate an immutable object

Summary 133

```
15
     println!("base: {:?}", base);
                                              Introduces a new scope
16
                                              where base can be
17
                                            mutably borrowed
18
19
       let mut base 2 = base.borrow mut();
      base 2.radio freq -= 12.34;
20
     println!("base 2: {:?}", base 2);
21
22
23
    println!("base: {:?}", base);
24
25
26
     let mut base 3 = base.borrow mut();
     base 3.radio freq += 43.21;
27
28
29 println!("base: {:?}", base);
   println!("base 3: {:?}", base 3);
3.0
31 }
```

There are two things to note from this example:

- Adding more functionality (e.g., reference-counting semantics rather than move semantics) to types by wrapping these in other types typically reduces their runtime performance.
- If implementing Clone would be prohibitively expensive, Rc<T> can be a handy alternative. This allows two places to "share" ownership.

NOTE Rc<T> is not thread-safe. In multithreaded code, it's much better to replace Rc<T> with Arc<T> and Rc<RefCell<T>> with Arc<Mutex<T>>. Arc stands for atomic reference counter.

Summary

- A value's owner is responsible for cleaning up after that value when its lifetime ends.
- A value's lifetime is the period when accessing that value is valid behavior. Attempting to access a value after its lifetime has expired leads to code that won't compile.
- To *borrow* a value means to access that value.
- If you find that the borrow checker won't allow your program to compile, several tactics are available to you. This often means that you will need to rethink the design of your program.
- Use shorter-lived values rather than values that stick around for a long time.
- Borrows can be read-only or read-write. Only one read-write borrow can exist at any one time.
- Duplicating a value can be a pragmatic way to break an impasse with the borrow checker. To duplicate a value, implement Clone or Copy.
- It's possible to opt in to reference counting semantics through Rc<T>.
- Rust supports a feature known as interior mutability, which enables types to present themselves as immutable even though their values can change over time.

Part 2

Demystifying systems programming

Part 2 extends your base Rust knowledge by applying Rust to examples from the field of systems programming. Every chapter includes at least one large project that includes a new language feature. You will build command-line utilities, libraries, graphical applications, networked applications, and even your own operating system kernel.

Data in depth

This chapter covers

- Learning how the computer represents data
- Building a working CPU emulator
- Creating your own numeric data type
- Understanding floating-point numbers

This chapter is all about understanding how zeroes and ones can become much larger objects like text, images, and sound. We will also touch on how computers do computation.

By the end of the chapter, you will have emulated a fully functional computer with CPU, memory, and user-defined functions. You will break apart floating-point numbers to create a numeric data type of your own that only takes a single byte. The chapter introduces a number of terms, such as *endianness* and *integer overflow*, that may not be familiar to programmers who have never done systems programming.

5.1 Bit patterns and types

A small but important lesson is that a single bit pattern can mean different things. The type system of a higher-level language, such as Rust, is just an artificial abstraction over reality. Understanding this becomes important as you begin to unravel some of that abstraction and to gain a deeper understanding of how computers work.

Listing 5.1 (in ch5-int-vs-int.rs) is an example that uses the same bit pattern to represent two different numbers. The type system—not the CPU—is what makes this distinction. The following shows the listing's output:

```
a: 1100001111000011 50115
b: 1100001111000011 -15421
```

Listing 5.1 The data type determines what a sequence of bits represents

```
1 fn main() {
2   let a: u16 = 50115;
3   let b: i16 = -15421;
4
5   println!("a: {:016b} {}", a, a);
6   println!("b: {:016b} {}", b, b);
7 }
These two values have the same bit pattern but different types.
```

The different mapping between bit strings and numbers explains part of the distinction between binary files and text files. Text files are just binary files that happen to follow a consistent mapping between bit strings and characters. This mapping is called an *encoding*. Arbitrary files don't describe their meaning to the outside world, which makes these opaque.

We can take this process one step further. What happens if we ask Rust to treat a bit pattern produced by one type as another? The following listing provides an answer. The source code for this listing is in ch5/ch5-f32-as-u32.rs.

Listing 5.2 Interpreting a float's bit string as an integer

```
1 fn main() {
                                               No semicolon here. We want the
 2 let a: f32 = 42.42;
                                               result of this expression to feed
     let frankentype: u32 = unsafe {
                                              into the outer scope.
     std::mem::transmute(a)
 4
 5
                                               Views the bits of a 42.42 f32
 6
                                              value as a decimal integer
     println!("{}", frankentype);
 7
 8
    println!("{:032b}", frankentype);
                                                      {:032b} means to format as a binary
 9
                                                     via the std::fmt::Binary trait with 32
10
    let b: f32 = unsafe {
                                                     zeroes padded on the left.
11
     std::mem::transmute(frankentype)
12 };
                                   Confirms that the
13 println!("{}", b);
                                  operation is symmetrical
    assert eq!(a, b);
14
15 }
```

When compiled and run, the code from listing 5.2 produces the following output:

```
1110027796
01000010001010011010111000010100
42.42
```

Some further remarks about some of the unfamiliar Rust that listing 5.2 introduces includes the following:

• Line 8 demonstrates a new directive to the println!() macro: {:032b}. The 032 reads as "left-pad with 32 zeros" and the right-hand b invokes the std::fmt::Binary trait. This contrasts with the default syntax ({}), which invokes the std::fmt::Display trait, or the question mark syntax ({:?}), which invokes std::fmt::Debug.

Unfortunately for us, f32 doesn't implement std::fmt::Binary. Luckily, Rust's integer types do. There are two integer types guaranteed to take up the same number of bits as f32—i32 and u32. The decision about which to choose is somewhat arbitrary.

• Lines 3–5 perform the conversion discussed in the previous bulleted point. The std:: mem::transmute() function asks Rust to naïvely interpret an f32 as an u32 without affecting any of the underlying bits. The inverse conversion is repeated later on lines 10–12.

Mixing data types in a program is inherently chaotic, so we need to wrap these operation within unsafe blocks. unsafe tells the Rust compiler, "Stand back, I'll take care of things from here. I've got this." It's a signal to the compiler that you have more context than it does to verify the correctness of the program.

Using the unsafe keyword does not imply that code is *inherently* dangerous. For example, it does not allow you to bypass Rust's borrow checker. It indicates that the compiler is not able to guarantee that the program's memory is safe by itself. Using unsafe means that the programmer is fully responsible for maintaining the program's integrity.

WARNING Some functionality allowed within unsafe blocks is more difficult to verify than others. For example, the std::mem::transmute() function is one of the least safe in the language. It shreds all type safety. Investigate alternatives before using it in your own code.

Needlessly using unsafe blocks is heavily frowned upon within the Rust community. It can expose your software to critical security vulnerabilities. Its primary purpose is to allow Rust to interact with external code, such as libraries written in other languages and OS interfaces. This book uses unsafe more frequently than many projects because its code examples are teaching tools, not industrial software. unsafe allows you to peek at and poke at individual bytes, which is essential knowledge for people seeking to understand how computers work.

5.2 Life of an integer

During earlier chapters, we spent some time discussing what it means for an integer to be an i32, an u8, or an usize. Integers are like small, delicate fish. They do what they do remarkably well, but take them outside of their natural range and they die a quick, painful death.

Integers live within a fixed range. When represented inside the computer, these occupy a fixed number of bits per type. Unlike floating-point numbers, integers cannot sacrifice their precision to extend their bounds. Once those bits have been filled with 1s, the only way forward is back to all 0s.

A 16-bit integer can represent numbers between 0 and 65,535, inclusive. What happens when you want to count to 65,536? Let's find out.

The technical term for the class of problem that we are investigating is *integer over-flow*. One of the most innocuous ways of overflowing an integer is by incrementing for-ever. The following listing (ch5/ch5-to-oblivion.rs) is a trivial example of this.

Listing 5.3 Exploring the effect of incrementing an integer past its range

```
1 fn main() {
 2 let mut i: u16 = 0;
   print!("{}..", i);
   loop {
 5
 6
   i += 1000;
 7
      print!("{}..", i);
      if i % 10000 == 0 {
 8
 9
           print!{"\n"}
    }
10
11
    }
12 }
```

When we try to run listing 5.3, things don't end well for our program. Let's look at the output:

A panicked program is a dead program. Panic means that the programmer has asked the program to do something that's impossible. It doesn't know what to do to proceed and shuts itself down.

To understand why this is such a critical class of bugs, let's take a look at what's going on under the hood. Listing 5.4 (ch5/ch5-bit-patterns.rs) prints six numbers with their bit patterns laid out in literal form. When compiled, the listing prints the following short line:

```
0, 1, 2, ..., 65533, 65534, 65535
```

Try compiling the code with optimizations enabled via rustc -0 ch5-to-oblivion.rs and running the resulting executable. The behavior is quite different. The problem we're interested in is what happens when there's no more bits left. 65,536 cannot be represented by u16.

Listing 5.4 How u16 bit patterns translate to a fixed number of integers

```
fn main() {
  let zero: u16 = 0b0000_0000_0000_0000;
  let one: u16 = 0b0000_0000_0000_0001;
  let two: u16 = 0b0000_0000_0000_010;
  // ...
  let sixtyfivethousand_533: u16 = 0b1111_1111_1111_1101;
  let sixtyfivethousand_534: u16 = 0b1111_1111_1111_1111;
  let sixtyfivethousand_535: u16 = 0b1111_1111_1111_1111;
  print!("{}, {}, {}, ..., ", zero, one, two);
  println!("{}, {}, {}", sixty5_533, sixty5_534, sixty5_535);
}
```

There is another (easy) way to kill a program using a similar technique. In listing 5.5, we ask Rust to fit 400 into an u8, which can only count up to 255 values. Look in ch5/ch5-impossible-addition.rs for the source code for this listing.

Listing 5.5 Impossible addition

```
#[allow(arithmetic_overflow)]
fn main() {
  let (a, b) = (200, 200);
  let c: u8 = a + b;
  println!("200 + 200 = {}", c);
}

Required declaration. The
Rust compiler can detect this
obvious overflow situation.

Without the type declaration, Rust
won't assume that you're trying to
create an impossible situation.
```

The code compiles, but one of two things happen:

• The program panics:

```
thread 'main' panicked at 'attempt to add with overflow',
   5-impossible-add.rs:3:15
note: Run with `RUST BACKTRACE=1` for a backtrace
```

This behavior can be invoked via executing rustc with its default options: rustc ch5-impossible-add.rs && ch5-impossible-add.

The program gives you the wrong answer:

```
200 + 200 = 144
```

This behavior can be invoked by executing rustc with the -O flag: rustc -O ch5-impossible-add.rs && ch5-impossible-add.

There are two small lessons here:

- It's important to understand the limitations of your types.
- Despite Rust's strengths, programs written in Rust can still break.

Developing strategies for preventing integer overflow is one of the ways that system programmers are distinguished from others. Programmers who only have experience with dynamic languages are extremely unlikely to encounter an integer overflow. Dynamic languages typically check to see that the results of integer expressions will fit. When these can't, the variable that's receiving the result is promoted to a wider integer type.

When developing performance critical code, you get to choose which parameters to adjust. If you use fixed-sized types, you gain speed, but you need to accept some risk. To mitigate the risk, you can check to see that overflow won't occur at runtime. Imposing those checks will slow you down, however. Another, much more common option, is to sacrifice space by using a large integer type, such as i64. To go higher still, you'll need to move to arbitrarily sized integers, which come with their own costs.

5.2.1 Understanding endianness

CPU vendors argue about how the individual bytes that make up integers should be laid out. Some CPUs order multibyte sequences left to right and others are right to left. This characteristic is known as a CPU's *endianness*. The is one of the reasons why copying an executable file from one computer to another might not work.

Let's consider a 32-bit integer that represents a number made up of four bytes: AA, BB, CC, and DD. Listing 5.6 (ch5/ch5-endianness.rs), with the help of our friend sys::mem::transmute(), demonstrates that byte order matters. When compiled and executed, the code from listing 5.6 prints one of two things, depending on the endianness of your machine. Most computers that people run for day-to-day work print the following:¹

```
-573785174 vs. -1430532899
```

But more exotic hardware swaps the two numbers around like this:

```
-1430532899 vs. -573785174
```

Listing 5.6 Inspecting endianness

```
use std::mem::transmute;
fn main() {
  let big_endian: [u8; 4] = [0xAA, 0xBB, 0xCC, 0xDD];
  let little_endian: [u8; 4] = [0xDD, 0xCC, 0xBB, 0xAA];
```

¹ In 2021, the x86-64/AMD64 CPU architecture is dominant.

```
let a: i32 = unsafe { transmute(big_endian) };
let b: i32 = unsafe { transmute(little_endian) };

println!("{} vs {}", a, b);
}
std::mem::transmute()
instructs the compiler to
interpret its argument as
the type on the left (i32).
```

The terminology comes from the *significance* of the bytes in the sequence. To take you back to when you learned addition, we can factor the number 123 into three parts:

100 × 1	100
10 × 2	20
1 × 3	3

Summing all of these parts gets us back to our original number. The first part, 100, is labeled as the most significant. When written out in the conventional way, 123 as 123, we are writing in *big endian* format. Were we to invert that ordering by writing 123 as 321, we would be writing in *little endian* format.

Binary numbers work in a similar way. Each number part is a power of 2 $(2^0, 2^1, 2^2, ..., 2n)$, rather than a power of 10 $(10^0, 10^1, 10^2, ..., 10n)$.

Before the late-1990s, endianness was a big issue, especially in the server market. Glossing over the fact that a number of processors can support bidirectional endianness, Sun Microsystems, Cray, Motorola, and SGI went one way. ARM decided to hedge its bet and developed a *bi-endian* architecture. Intel went the other way. The other way won. Integers are almost certainly stored in *little endian* format.

In addition to multibyte sequences, there is a related problem within a byte. Should an u8 that represents 3 look like 0000_0011, or should it look like 1100_0000? The computer's preference for layout of individual bits is known as its *bit numbering* or *bit endianness*. It's unlikely, however, that this internal ordering will affect your day-to-day programming. To investigate further, look for your platform's documentation to find out on which end its *most significant* bit lies.

NOTE The abbreviation MSB can be deceptive. Different authors use the same abbreviation to refer to two concepts: most significant *bit* and most significant *byte*. To avoid confusion, this text uses the term *bit numbering* to refer to the most significant bit and *endianness* to refer to most significant byte.

5.3 Representing decimal numbers

One of the claims made at the start of this chapter was that understanding more about bit patterns enables you to compress your data. Let's put that into practice. In this section, you will learn how to pull bits out of a floating-point number and inject those into a single byte format of your own creation.

Here is some context for the problem at hand. Machine learning practitioners often need to store and distribute large models. A model for our purposes here is just

a large array of numbers. The numbers within those models often fall within the ranges 0..=1 or -1..=1 (using Rust's range syntax), depending on the application. Given that we don't need the whole range that £32 or £64 supports, why use all of these bytes? Let's see how far we can get with 1. Because there is a known limited range, it's possible to create a decimal number format that can model that range compactly.

To start, we're going to need to learn about how decimal numbers are represented inside today's computers. This means learning about the internals of floating-point numbers.

5.4 Floating-point numbers

Each floating-point number is laid out in memory as scientific notation. If you're unfamiliar with scientific notation, here is a quick primer.

Scientists describe the mass of Jupiter as 1.898×10^{27} kg and the mass of an ant as 3.801×10^{-4} kg. The key insight is that the same number of characters are used to describe vastly different scales. Computer scientists have taken advantage of that insight to create a fixed-width format that encodes a wide range of numbers. Each position within a number in scientific notation is given a role:

- A *sign*, which is implied in our two examples, would be present for negative numbers (negative infinity to 0).
- The *mantissa*, also known as the *significand*, can be thought of as being the value in question (1.898 and 3.801, for example).
- The *radix*, also known as the *base*, is the value that is raised to the power of the exponent (10 in both of our examples).
- The *exponent* describes the scale of the values (27 and –4).

This crosses over to floating point quite neatly. A floating-point value is a container with three fields:

- A sign bit
- An exponent
- A mantissa

Where is the radix? The standard defines it as 2 for all floating-point types. This definition allows the radix to be omitted from the bit pattern itself.

5.4.1 Looking inside an f32

Figure 5.1 presents the memory layout of the £32 type in Rust. The layout is called *binary32* within the IEEE 754-2019 and IEEE 754-2008 standards and *single* by their predecessor, IEE 754-1985.

The value 42.42 is encoded as f32 with the bit pattern 010000100010101111000010100. That bit pattern is more compactly represented as 0x4229AE14. Table 5.1 shows the values of each of the three fields and what these represent..

Figure 5.1 An overview of the three components encoded within the bits of a floating-point number for the £32 type in Rust

Table 5.1 The components of 42.42 represented by the bit pattern 0x4229AE14 as a f32 type

Component name	Component in binary	Component as base-10 (u32)	Decoded value
Sign bit (s)	0	0	1
Exponent (t)	10000100	132	5
Mantissa/significand (m)	01010011010111000010100	2,731,540	1.325625
Base/radix			2
Exponent bias			127

NOTE See listing 5.9 for an explanation provided of how the bit pattern 01010011010111000010100 represents 1.325625.

The following equation decodes the fields of a floating-point number into a single number. Variables from the standard (Radix, Bias) appear in title case. Variables from the bit pattern (sign bit, mantissa, exponent) occur as lowercase and monospace.

```
\begin{split} n &= -1^{\text{sign\_bit}} \times \text{mantissa} \times \text{Radix}^{\text{(exponent-Bias)}} \\ n &= -1^{\text{sign\_bit}} \times \text{mantissa} \times \text{Radix}^{\text{(exponent-127)}} \\ n &= -1^{\text{sign\_bit}} \times \text{mantissa} \times \text{Radix}^{\text{(132-127)}} \\ n &= -1^{\text{sign\_bit}} \times \text{mantissa} \times 2^{\text{(132-127)}} \\ n &= -1^{\text{sign\_bit}} \times 1.325625 \times 2^{\text{(132-127)}} \\ n &= -1^0 \times 1.325625 \times 2^5 \\ n &= 1 \times 1.325625 \times 32 \\ n &= 42.42 \end{split}
```

One quirk of floating-point numbers is that their sign bits allow for both 0 and -0. That is, floating-point numbers that have different bit patterns compare as equal (0 and -0) and have identical bit patterns (NAN values) that compare as unequal.

5.4.2 Isolating the sign bit

To isolate the sign bit, shift the other bits out of the way. For £32, this involves a right shift of 31 places (>> 31). The following listing is a short snippet of code that performs the right shift.

Listing 5.7 Isolating and decoding the sign bit from an £32

```
1 let n: f32 = 42.42;
2 let n_bits: u32 = n.to_bits();
3 let sign bit = n bits >> 31;
```

To provide you with a deeper intuition about what is happening, these steps are detailed graphically here:

1 Start with a f32 value:

```
1 let n: f32 = 42.42;
```

2 Interpret the bits of the f32 as a u32 to allow for bit manipulation:

```
2 let n bits: u32 = n.to bits();
```

The issue that needs to be resolved is the sign bit's position. Treated naïvely, it represents 4,294,967,296 (2^{32}) or 0, rather than 1 (2^{0}) or 0.

3 Shift the bits within n 31 places to the right:

```
3 let sign_bit = n_bits >> 31;

The sign bit has now been moved to _____
the least significant position.
```

5.4.3 Isolating the exponent

To isolate the exponent, two bit manipulations are required. First, perform a right shift to overwrite the mantissa's bits (>> 23). Then use an AND mask (& 0xff) to exclude the sign bit.

The exponent's bits also need to go through a decoding step. To decode the exponent, interpret its 8 bits a signed integer, then subtract 127 from the result. (As shown in table 5.1, 127 is known as the *bias*.) The following listing shows the code that describes the steps given in the last two paragraphs.

Listing 5.8 Isolating and decoding the exponent from an £32

```
1 let n: f32 = 42.42;
2 let n_bits: u32 = n.to_bits();
3 let exponent_ = n_bits >> 23;
4 let exponent_ = exponent_ & 0xff;
5 let exponent = (exponent as i32) - 127;
```

And to further explain the process, these steps are repeated graphically as follows:

1 Start with an f32 number:

```
1 let n: f32 = 42.42;
```

2 Interpret the bits of that £32 as u32 to allow for bit manipulation:

```
2 let n bits: u32 = n.to bits();
```

Problem: exponent bits are not aligned to the right.

3 Shift the exponent's 8 bits to the right, overwriting the mantissa:

```
3 let exponent_ = n_bits >> 23;
```

Problem: The sign bit remains at bit 8.

4 Filter the sign bit away with an AND mask. Only the 8 rightmost bits can pass through the mask:

```
4 let exponent_ = exponent_ & 0xff;
```

The sign bit has now been removed.

5 Interpret the remaining bits as a signed integer and subtract the bias as defined by the standard:

```
5 let exponent = (exponent_ as i32) - 127;
```

5.4.4 Isolate the mantissa

To isolate the mantissa's 23 bits, you can use an AND mask to remove the sign bit and the exponent (& 0x7ffffff). However, it's actually not necessary to do so because the following decoding steps can simply ignore bits as irrelevant. Unfortunately, the mantissa's decoding step is significantly more complex than the exponent's.

To decode the mantissa's bits, multiply each bit by its weight and sum the result. The first bit's weight is 0.5, and each subsequent bit's weight is half of the current weight; for example, 0.5 (2^{-1}), 0.25 (2^{-2}),..., 0.00000011920928955078125 (2^{-23}). An implicit 24th bit that represents 1.0 (2^{-0}) is always considered to be on, except when special cases are triggered. Special cases are triggered by the state of the exponent:

- When the exponent's bits are all 0s, then the treatment of mantissa's bits changes to represent subnormal numbers (also known as "denormal numbers"). In practical terms, this change increases the number of decimal numbers near zero that can be represented. Formally, a subnormal number is one between 0 and the smallest number that the normal behavior would otherwise be able to represent.
- When the exponent's bits are all 1s, then the decimal number is infinity (∞), negative infinity ($-\infty$), or Not a Number (NAN). NAN values indicate special cases where the numeric result is mathematically undefined (such as $0 \div 0$) or that are otherwise invalid.

Operations involving NAN values are often counterintuitive. For example, testing whether two values are equal is always false, even when the two bit patterns are exactly the same. An interesting curiosity is that f32 has approximately 4.2 million (\sim 2 22) bit patterns that represent NAN.

The following listing provides the code that implements nonspecial cases.

Listing 5.9 Isolating and decoding the mantissa from an £32

```
1 let n: f32 = 42.42;
 2 let n bits: u32 = n.to bits();
 3 let mut mantissa: f32 = 1.0;
 5 for i in 0..23 {
     let mask = 1 << i;
 7
     let one at bit i = n bits & mask;
     if one at bit i != 0 {
         let i = i as f32;
9
10
         let weight = 2 f32.powf( i - 23.0 );
11
         mantissa += weight;
     }
12
13 }
```

Repeating that process slowly:

1 Start with an £32 value:

```
1 let n: f32 = 42.42;
```

2 Cast f32 as u32 to allow for bit manipulation:

```
2 let n bits: u32 = n.to bits();
```

3 Create a mutable f32 value initialized to $1.0 (2^{-0})$. This represents the weight of the implicit 24th bit:

```
3 let mut mantissa: f32 = 1.0;
```

4 Iterate through the fractional bits of the mantissa, adding those bit's defined values to the mantissa variable:

```
5 for i in 0..23 {
6    let mask = 1 << i;
7    let one_at_bit_i = n_bits & mask;
8    if one_at_bit_i != 0 {
9        let i_ = i as f32;
10        let weight = 2_f32.powf(i_ - 23.0);
11        mantissa += weight;
12    }
13 }</pre>
```

a Iterate from 0 to 23 with a temporary variable i assigned to the iteration number:

```
5 for i in 0..23 {
```

b Create a bit mask with the iteration number as the bit allowed to pass through and assign the result to mask. For example, when i equals 5, the bit mask is 0b00000000 00000000 00000000 001000000:

```
6 let mask = 1 << i;
```

Use mask as a filter against the bits from the original number stored as n_bits. When the original number's bit at position i is non-zero, one_at_ bit i will be assigned to a non-zero value:

```
7 let one_at_bit_i = n_bits & mask;
```

d If one at bit i is non-zero, then proceed:

```
8 if one_at_bit_i != 0 {
```

e Calculate the weight of the bit at position i, which is $2i^{-23}$:

```
9 let i_ = i as f32;
10 let weight = 2 f32.powf( i - 23.0 );
```

f Add the weight to mantissa in place:

```
11 mantissa += weight;
```

Parsing Rust's floating-point literals is harder than it looks

Rust's numbers have methods. To return the nearest integer to 1.2, Rust uses the method $1.2_f32.ceil()$ rather than the function call ceil(1.2). While often convenient, this can cause some issues when the compiler parses your source code.

For example, unary minus has lower precedence than method calls, which means unexpected mathematical errors can occur. It is often helpful to use parentheses to make your intent clear to the compiler. To calculate -1° , wrap 1.0 in parentheses

```
(-1.0_f32).powf(0.0)

rather than

-1.0_f32.powf(0.0)
```

which is interpreted as $-(1^0)$. Because both -1^0 and $-(1^0)$ are mathematically valid, Rust will not complain when parentheses are omitted.

5.4.5 Dissecting a floating-point number

As mentioned at the start of section 5.4, floating-point numbers are a container format with three fields. Sections 5.4.1–5.4.3 have given us the tools that we need to extract each of these fields. Let's put those to work.

Listing 5.10 does a round trip. It extracts the fields from the number 42.42 encoded as an £32 into individual parts, then assembles these again to create another number. To convert the bits within a floating-point number to a number, there are three tasks:

- 1 Extract the bits of those values from the container (to parts() on lines 1-26)
- 2 Decode each value from its raw bit pattern to its actual value (decode() on lines 28–47)
- 3 Perform the arithmetic to convert from scientific notation to an ordinary number (from parts () on lines 49–55)

When we run listing 5.10, it provides two views of the internals of the number 42.42 encoded as an f32:

```
42.42 -> 42.42
field | as bits | as real number
sign | 0 | 1
exponent | 10000100 | 32
mantissa | 01010011010111000010100 | 1.325625
```

In listing 5.10, deconstruct_f32() extracts each field of a floating-point value with bit manipulation techniques. decode_f32_parts() demonstrates how to convert those fields to the relevant number. The f32_from_parts() method combines these to create a single decimal number. The source for this file is located in ch5/ch5-visualizing-f32.rs.

Listing 5.10 Deconstructing a floating-point value

```
1 const BIAS: i32 = 127;
                                                   Similar constants are accessible
               2 const RADIX: f32 = 2.0;

```

Understanding how to unpack bits from bytes means that you'll be in a much stronger position when you're faced with interpreting untyped bytes flying in from the network throughout your career.

5.5 Fixed-point number formats

In addition to representing decimal numbers with floating-point formats, fixed point is also available. These can be useful for representing fractions and are an option for performing calculations on CPUs without a floating point unit (FPU), such as microcontrollers. Unlike floating-point numbers, the decimal place does not move to dynamically accommodate different ranges. In our case, we'll be using a fixed-point number format to compactly represent values between -1..=1. Although it loses accuracy, it saves significant space.²

The Q format is a fixed-point number format that uses a single byte.³ It was created by Texas Instruments for embedded computing devices. The specific version of the Q format that we will implement is called Q7. This indicates that there are 7 bits available for the represented number plus 1 sign bit. We'll disguise the decimal nature of the type by hiding the 7 bits within an i8. That means that the Rust compiler will be able to assist us in keeping track of the value's sign. We will also be able to derive traits such as PartialEq and Eq, which provide comparison operators for our type, for free.

The following listing, an extract from listing 5.14, provides the type's definition. You'll find the source in ch5/ch5-q/src/lib.rs.

Listing 5.11 Definition of the Q7 format

A struct created from unnamed fields (for example, Q7(i8)), is known as a *tuple struct*. It offers a concise notation when the fields are not intended to be accessed directly. While not shown in listing 5.11, tuple structs can include multiple fields by adding further types separated by commas. As a reminder, the #[derive(...)] block asks Rust to implement several traits on our behalf:

² This practice is known as *quantizing the model* in the machine learning community.

³ *Q*, often written as \mathbb{Q} (this style is called *blackboard bold*), is the mathematical symbol for the so-called rational numbers. Rational numbers are numbers that can be represented as a fraction of two integers, such as 1/3.

- Debug—Used by the println! () macro (and others); allows Q7 to be converted to a string by the {:?} syntax.
- Clone—Enables Q7 to be duplicated with a .clone() method. This can be derived because i8 implements the Clone trait.
- Copy—Enables cheap and implicit duplications where ownership errors might otherwise occur. Formally, this changes Q7 from a type that uses *move semantics* to one that uses *copy semantics*.
- PartialEq—Enables Q7 values to be compared with the equality operator (==).
- Eq—Indicates to Rust that all possible Q7 values can be compared against any other possible Q7 value.

Q7 is intended as a compact storage and data transfer type only. Its most important role is to convert to and from floating-point types. The following listing, an extract from listing 5.14, shows the conversion to £64. The source for this listing is in ch5/ch5-q/src/lib.rs.

Listing 5.12 Converting from £64 to Q7

```
4 impl From<f64> for Q7 {
 5 fn from (n: f64) -> Self {
 6
           // assert!(n >= -1.0);
 7
           // assert!(n <= 1.0);
          if n >= 1.0 {
 8

               Q7((n * 128.0) as i8)
14
15
       }
16 }
17
                                                      Equivalent to the
18 impl From<Q7> for f64 {
                                                      iteration approach
19
      fn from(n: O7) -> f64 {
                                                      taken in listing 5.9.
           (n.0 as f64) * 2 f64.powf(-7.0)
2.0
21
22 }
```

The two impl From<T> for U blocks in listing 5.12 explain to Rust how to convert from type T to type U. In the listing

• Lines 4 and 18 introduce the impl From<T> for U blocks. The std::convert ::From trait is included in local scope as From, which is part of the standard prelude. It requires type U to implement from() that takes a T value as its sole argument.

- Lines 6–7 present an option for handling unexpected input data: crashes. It is not used here, but is available to you in your own projects.
- Lines 13–16 truncate out-of-bounds input. For our purposes, we know that out-of-bounds input will not occur and so accept the risk of losing information.

TIP Conversions using the From trait should be mathematically equivalent. For type conversions that can fail, consider implementing the std::convert::TryFrom trait instead.

We can also quickly implement converting from £32 to Q7 using the From<£64> implementation that we've just seen. The following listing, an extract from listing 5.14, shows this conversion. Its source is in ch5/ch5-q/src/lib.rs.

Listing 5.13 Converting from £32 to Q7 via £64

Now, we've covered both floating-point types. But how do we know that the code that we've written actually does what we intend? And how do we test what we've written? As it happens, Rust has excellent support for unit testing via cargo.

The Q7 code that you've seen is available as a complete listing. But first, to test the code, enter the root directory of the crate and run cargo test. The following shows the output from listing 5.14 (the complete listing):

\$ cargo test

```
Compiling ch5-q v0.1.0 (file:///path/to/ch5/ch5-q)
Finished dev [unoptimized + debuginfo] target(s) in 2.86 s
Running target\debug\deps\ch5_q-013c963f84b21f92

running 3 tests
test tests::f32_to_q7 ... ok
test tests::out_of_bounds ... ok
test tests::q7_to_f32 ... ok
```

```
test result: ok. 3 passed; 0 failed; 0 ignored; 0 measured; 0 filtered out
   Doc-tests ch5-q
running 0 tests
test result: ok. 0 passed; 0 failed; 0 ignored; 0 measured; 0 filtered out
```

The following listing implements the Q7 format and its conversion to and from £32 and £64 types. You'll find the source for this listing in ch5/ch5-q/src/lib.rs.

Listing 5.14 Full code implementation of the Q7 format

```
1 #[derive(Debug, Clone, Copy, PartialEq, Eq)]
 2 pub struct Q7(i8);
 4 impl From<f64> for Q7 {
     fn from (n: f64) -> Self {
          if n >= 1.0 {
 6
              Q7(127)
 7
 8
          } else if n <= -1.0 {
 9
              Q7(-128)
          } else {
10
11

61
        let n1 = f32::from(q1);
         assert_eq!(n1, 0.6953125);
65
         let q2 = Q7::from(n1);
         let n2 = f32::from(q2);
67
          assert eq!(n1, n2);
       }
68
69 }
```

A brief look at Rust's module system

Rust includes a powerful and ergonomic module system. To keep the examples simple, however, this book does not make heavy use of its system. But here are some basic guidelines:

- Modules are combined into crates.
- Modules can be defined by a project's directory structure. Subdirectories under src/ become a module when that directory contains a mod.rs file.
- Modules can also be defined within a file with the mod keyword.
- Modules can be nested arbitrarily.
- All members of a module including its submodules are private by default. Private items can be accessed within the module and any of the module's descendants.

- Prefix things that you want to make public with the pub keyword. The pub keyword has some specialized cases:
 - a pub (crate) exposes an item to other modules within the crate.
 - b pub (super) exposes an item to the parent module.
 - c pub (in path) exposes an item to a module within path.
 - d pub(self) explicitly keeps the item private.
- Bring items from other modules into local scope with the use keyword.

5.6 Generating random probabilities from random bytes

Here is an interesting exercise to test the knowledge that you have developed over the preceding pages. Imagine that you have a source of random bytes (u8), and you want to convert one of those into a floating-point (f32) value between 0 and 1. Naively interpreting the incoming bytes as f32/f64 via mem::transmute results in massive variations in scale. The following listing demonstrates the division operation that generates an f32 value that lies between 0 and 1 from an arbitrary input byte.

Listing 5.15 Generating f32 values in interval [0,1] from a u8 with division

As division is a slow operation, perhaps there is something faster than simply dividing by the largest value that a byte can represent. Perhaps it's possible to assume a constant exponent value, then shift the incoming bits into the mantissa, such that these would form a range between 0 and 1. Listing 5.16 with bit manipulation is the best result that I could achieve.

With an exponent of –1 represented as 0b011111110 (126 in base 10), the source byte achieves a range of 0.5 to 0.998. That can be normalized to 0.0 to 0.996 with subtraction and multiplication. But is there a better way to do this?

Listing 5.16 Generating f32 values in interval [0,1] from a u8

```
1 fn mock rand(n: u8) -> f32 {
2
      3
4
                                               Aligns the input byte n to 32 bits.
5
      let large n = (n \text{ as u32}) << 15;
                                              then increases its value by shifting
6
                                             its bits 15 places to the left
      7
                                             Takes a bitwise OR, merging
    let m = f32::from_bits(f32_bits); <---</pre>
9
                                           the base with the input byte
1.0
11
      2.0 * ( m - 0.5 )
                                          Interprets f32_bits (which
12 }
                 Normalizes the
                                          is type u32) as an f32
                  output range
```

As a complete program, you can incorporate $mock_rand()$ from listing 5.16 into a test program fairly easily. Listing 5.17 (ch5/ch5-u8-to-mock-rand.rs) generates an f32 value that lies between 0 and 1 from an arbitrary input byte without division. Here's its output:

```
max of input range: 11111111 -> 0.99609375
mid of input range: 01111111 -> 0.49609375
min of input range: 00000000 -> 0
```

Listing 5.17 Generating an £32 value without division

5.7 Implementing a CPU to establish that functions are also data

One of the fairly mundane, yet utterly intriguing details about computing is that instructions are also just numbers. Operations and the data that is being operated on share the same encoding. This means that, as a general computing device, your computer can emulate other computers' *instruction sets* by emulating those in software. While we cannot pull apart a CPU to see how it works, we can construct one with code.

After working through this section, you will learn how a computer operates at a fundamental level. This section shows how functions operate and what the term *pointer* means. We won't have an assembly language; we'll actually be programming directly in hex. This section also introduces you to another term you may have heard of in passing: *the stack*.

We'll implement a subset of a system called CHIP-8, which was available to consumers in the 1970s. CHIP-8 was supported by a number of manufacturers, but it was fairly primitive even by the standards of that time. (It was created to write games rather than for commercial or scientific applications.)

One device that used the CHIP-8 CPU was the COSMAC VIP. It had a single-color display with a resolution of 64x32 (0.0002 megapixels), 2 KB RAM, 1.76 MHz CPU, and sold for \$275 USD. Oh, and you needed to assemble the computer yourself. It also contained games programmed by the world's first female game developer, Joyce Weisbecker.

5.7.1 CPU RIA/1: The Adder

We'll build our understanding by starting with a minimal core. Let's first construct an emulator that only supports a single instruction: addition. To understand what's happening within listing 5.22 later in this section, there are three main things to learn:

- Becoming familiar with new terminology
- How to interpret opcodes
- Understanding the main loop

TERMS RELATED TO CPU EMULATION

Dealing with CPUs and emulation involves learning some terms. Take a moment to look at and understand the following:

- An operation (often shortened to "op") refers to procedures that are supported natively by the system. You might also encounter equivalent phrases such as implemented in hardware or intrinsic operation as you explore further.
- Registers are containers for data that the CPU accesses directly. For most operations, operands must be moved to registers for an operation to function. For the CHIP-8, each register is a u8 value.
- *An opcode is a number that maps to an operation.* On the CHIP-8 platform, opcodes include both the operation and the operands' registers.

DEFINING THE CPU

The first operation that we want to support is addition. The operation takes two registers (x and y) as operands and adds the value stored in y to x. To implement this, we'll use the minimal amount of code possible, as the following listing shows. Our initial CPU contains only two registers and the space for a single opcode.

Listing 5.18 Definition of the CPU used in listing 5.22

```
struct CPU {

current_operation: u16,

registers: [u8; 2],

These two registers are sufficient for addition.
```

So far, the CPU is inert. To perform addition, we'll need to take the following steps, but there is no ability to store data in memory as yet:

- Initialize a CPU.
- 2 Load u8 values into registers.
- 3 Load the addition opcode into current operation.
- 4 Perform the operation.

LOADING VALUES INTO REGISTERS

The process for booting up the CPU consists of writing to the fields of the CPU struct. The following listing, an extract from listing 5.22, shows the CPU initialization process.

Listing 5.19 Initializing the CPU

```
32 fn main() {
                                         Initializes with a
   let mut cpu = CPU {
                                         no-op (do nothing)
     current operation: 0,
35
      registers: [0; 2],
36
37
     cpu.current operation = 0x8014;
38
39
     cpu.registers[0] = 5;
                                     Registers can only
     cpu.registers[1] = 10;
                                     hold u8 values.
```

Line 38 from listing 5.19 is difficult to interpret without context. The constant 0x8014 is the opcode that the CPU will interpret. To decode it, split it into four parts:

- 8 signifies that the operation involves two registers.
- 0 maps to cpu.registers[0].
- 1 maps to cpu.registers[1].
- 4 indicates addition.

UNDERSTANDING THE EMULATOR'S MAIN LOOP

Now that we've loaded the data, the CPU is almost able to do some work. The run() method performs the bulk of our emulator's work. Using the following steps, it emulates CPU cycles:

- 1 Reads the opcode (eventually, from memory)
- 2 Decodes instruction
- 3 Matches decoded instruction to known opcodes
- 4 Dispatches execution of the operation to a specific function

The following listing, an extract from listing 5.22, shows the first functionality being added to the emulator.

Listing 5.20 Reading the opcode

```
6 impl CPU {
     fn read opcode(&self) -> u16 {
                                             read opcode() becomes more
 8
       self.current operation
                                             complex when we introduce
                                             reading from memory.
 9
10
                                                Avoids running this
11
     fn run(&mut self) {
                                                code in a loop for now
      // loop {
12
13
         let opcode = self.read opcode();
14
15
          let c = ((opcode & 0xF000) >> 12) as u8;
                                                              The opcode decoding
16
         let x = ((opcode & 0x0F00) >> 8) as u8;
                                                              process is explained fully
17
         let y = ((opcode & 0x00F0) >> 4) as u8;
                                                              in the next section.
         let d = ((opcode & 0x000F) >> 0) as u8;
18
19
                                                                  Dispatches execution to the
20
         match (c, x, y, d) {
                                                                  hardware circuit responsible
21
              (0x8, _, _, 0x4) => self.add_xy(x, y),
                                                                 for performing it
```

```
22
                  => todo! ("opcode {:04x}", opcode),
                                                                        A full emulator
23
                                                                        contains several
24
                                                                        dozen operations.
                        Avoids running this
25
                        code in a loop for now
26
     fn add xy(&mut self, x: u8, y: u8) {
27
       self.registers[x as usize] += self.registers[y as usize];
28
29
30 }
```

How to interpret CHIP-8 opcodes

It is important for our CPU to be able to interpret its opcode (0x8014). This section provides a thorough explanation of the process used in the CHIP-8 and its naming conventions.

CHIP-8 opcodes are u16 values made up of 4 nibbles. A *nibble* is half of a byte. That is, a nibble is a 4-bit value. Because there isn't a 4-bit type in Rust, splitting the u16 values into those parts is fiddly. To make matters more complicated, CHIP-8 nibbles are often recombined to form either 8-bit or 12-bit values depending on context.

To simplify talking about the parts of each opcode, let's introduce some standard terminology. Each opcode is made up of two bytes: the *high byte* and the *low byte*. And each byte is made up of two nibbles, the *high nibble* and the *low nibble*, respectively. Figure 5.2 illustrates each term.

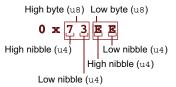

Figure 5.2 Terms used to refer to parts of CHIP-8 opcodes

Documentation manuals for the CHIP-8 introduce several variables, including kk, nnn, x, and y. Table 5.2 explains their role, location, and width.

Table 5.2 Variable	s used within	CHIP-8 op	code descriptions
--------------------	---------------	-----------	-------------------

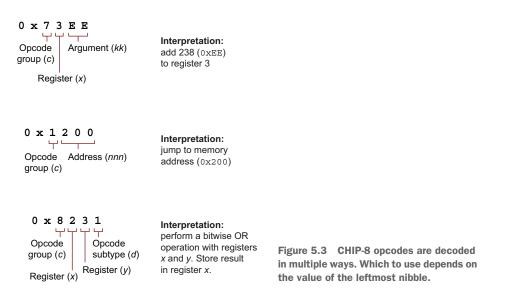

Variable	Bit length	Location	Description
n*	4	low byte, low nibble	Number of bytes
X	4	high byte, low nibble	CPU register
у	4	low byte, high nibble	CPU register
c^{\dagger}	4	high byte, high nibble	Opcode group
$a^{\dagger * \dagger}$	4	low byte, low nibble	Opcode subgroup
kk [‡]	8	low byte, both nibbles	Integer

Table 5.2 Variables used within CHIP-8 opcode descriptions (continued)

Variable	Bit length	Location	Description
nnn [†]	12	high byte, low nibble and low byte, both nibbles	Memory address

^{*} n and d occupy the same location but are used in mutually exclusive contexts.

There are three main forms of opcodes, as illustrated in figure 5.3. The decoding process involves matching on the high nibble of the first byte and then applying one of three strategies.

To extract nibbles from bytes, we'll need to use the right shift (>>) and logical AND (&) bitwise operations. These operations were introduced in section 5.4, especially in sections 5.4.1–5.4.3. The following listing demonstrates applying these bitwise operations to the current problem.

Listing 5.21 Extracting variables from an opcode

```
fn main() {
  let opcode: u16 = 0x71E4;

  let c = (opcode & 0xF000) >> 12;
  let x = (opcode & 0x0F00) >> 8;
  let y = (opcode & 0x00F0) >> 4;
  let d = (opcode & 0x00F) >> 0;

  let d = (opcode & 0x00F) >> 0;
```

[†] The variable names c and d are used within this book but not in other CHIP-8 documentation.

[†] Used in CPU RIA/3 (listing 5.29).

```
assert eq!(c, 0x7);
                                 The four nibbles from opcode are
assert eq!(x, 0x1);
                                 available as individual variables
assert eq!(y, 0xE);
                                 after processing.
assert eq!(d, 0x4);
                                      Select multiple nibbles by
let nnn = opcode & 0x0FFF;
let kk = opcode & 0x00FF;
                                      increasing the width of the
                                      filter. For our purposes,
                                      shifting bits rightward is
assert eq!(nnn, 0x1E4);
                                      unnecessary.
assert eq!(kk, 0xE4);
```

We're now able to decode the instructions. The next step is actually executing these.

5.7.2 Full code listing for CPU RIA/1: The Adder

The following listing is the full code for our proto-emulator, the Adder. You'll find its source in ch5/ch5-cpu1/src/main.rs.

Listing 5.22 Implementing the beginnings of CHIP-8 emulator

```
1 struct CPU {
 2 current operation: u16,
    registers: [u8; 2],
 4 }
 5
 6 impl CPU {
 7
    fn read opcode(&self) -> u16 {
 8
     self.current operation
 9
10
11
   fn run(&mut self) {
     // loop {
       let opcode = self.read opcode();
13
14
15
      let c = ((opcode & 0xF000) >> 12) as u8;
       let x = ((opcode \& 0x0F00) >> 8) as u8;
17
        let y = ((opcode & 0x00F0) >> 4) as u8;
18
        let d = ((opcode & 0x000F) >> 0) as u8;
19
        match(c, x, y, d)
           (0x8, _{-}, _{-}, 0x4) => self.add_xy(x, y),
21
22
             => todo!("opcode {:04x}", opcode),
23
      // }
24
     }
25
26
     fn add xy(&mut self, x: u8, y: u8) {
27
       self.registers[x as usize] += self.registers[y as usize];
28
29
30 }
31
32 fn main() {
33 let mut cpu = CPU {
```

```
current operation: 0,
34
35
     registers: [0; 2],
36
    };
37
38
    cpu.current operation = 0x8014;
    cpu.registers[0] = 5;
39
    cpu.registers[1] = 10;
40
41
42
    cpu.run();
43
44
     assert eq!(cpu.registers[0], 15);
45
     println!("5 + 10 = {}", cpu.registers[0]);
46
47 }
```

The Adder doesn't do much. When executed, it prints the following line:

```
5 + 10 = 15
```

5.7.3 CPU RIA/2: The Multiplier

CPU RIA/1 can execute a single instruction: addition. CPU RIA/2, the Multiplier, can execute several instructions in sequence. The Multiplier includes RAM, a working main loop, and a variable that indicates which instruction to execute next that we'll call position_in_memory. Listing 5.26 makes the following substantive changes to listing 5.22:

- Adds 4 KB of memory (line 8).
- Includes a fully-fledged main loop and stopping condition (lines 14–31).

At each step in the loop, memory at position_in_memory is accessed and decoded into an opcode. position_in_memory is then incremented to the next memory address, and the opcode is executed. The CPU continues to run forever until the stopping condition (an opcode of 0x0000) is encountered.

- Removes the current_instruction field of the CPU struct, which is replaced by a section of the main loop that decodes bytes from memory (lines 15–17).
- Writes the opcodes into memory (lines 51–53).

EXPANDING THE CPU TO SUPPORT MEMORY

We need to implement some modifications to make our CPU more useful. To start, the computer needs memory.

Listing 5.23, an extract from listing 5.26, provides CPU RIA/2's definition. CPU RIA/2 contains general-purpose registers for calculations (registers) and one special-purpose register (position_in_memory). For convenience, we'll also include the system's memory within the CPU struct itself as the memory field.

Listing 5.23 Defining a CPU struct

```
1 struct CPU {
2 registers: [u8; 16],
```

```
3 position_in_memory: usize,
4 memory: [u8; 0x1000],
5 }
Using usize rather that u16 diverges from the original spec, but we'll use usize as Rust allows these to be used for indexing.
```

Some features of the CPU are quite novel:

- Having 16 registers means that a single hexadecimal number (0 to F) can address those.
 That allows all opcodes to be compactly represented as u16 values.
- The CHIP-8 only has 4096 bytes of RAM (0x1000 in hexadecimal). This allows CHIP-8's equivalent of a usize type to only be 12 bits wide: $2^{12} = 4,096$. Those 12 bits become the nnn variable discussed earlier.

Rust in Action deviates from standard practice in two ways:

- What we call the "position in memory" is normally referred to as the "program counter." As a beginner, it can be difficult to remember what the program counter's role is. So instead, this book uses a name that reflects its usage.
- Within the CHIP-8 specification, the first 512 bytes (0x100) are reserved for the system, while other bytes are available for programs. This implementation relaxes that restriction.

READING OPCODES FROM MEMORY

With the addition of memory within the CPU, the read_opcode() method requires updating. The following listing, an extract from listing 5.26, does that for us. It reads an opcode from memory by combining two u8 values into a single u16 value.

Listing 5.24 Reading an opcode from memory

```
8 fn read_opcode(&self) -> u16 {
9    let p = self.position_in_memory;
10    let op_byte1 = self.memory[p] as u16;
11    let op_byte2 = self.memory[p + 1] as u16;
12
13    op_byte1 << 8 | op_byte2
14 }
To create a u16 opcode, we combine two values from memory with the logical OR operation. These need to be cast as u16 to start with; otherwise, the left shift sets all of the bits to 0.</pre>
```

HANDLING INTEGER OVERFLOW

Within the CHIP-8, we use the last register as a *carry flag*. When set, this flag indicates that an operation has overflowed the u8 register size. The following listing, an extract from listing 5.26, shows how to handle this overflow.

Listing 5.25 Handling overflow in CHIP-8 operations

```
The overflowing add()
34 fn add xy(&mut self, x: u8, y: u8) {
                                                                    method for u8 returns
   let arg1 = self.registers[x as usize];
35
                                                                    (u8, bool). The bool is
     let arg2 = self.registers[y as usize];
36
                                                                    true when overflow is
37
                                                                    detected.
     let (val, overflow) = arg1.overflowing add(arg2);
38
     self.registers[x as usize] = val;
39
40
```

```
41  if overflow {
42    self.registers[0xF] = 1;
43  } else {
44    self.registers[0xF] = 0;
45  }
46 }
```

FULL CODE LISTING FOR CPU RIA/2: THE MULTIPLIER

The following listing shows the complete code for our second working emulator, the Multiplier. You'll find the source for this listing in ch5/ch5-cpu2/src/main.rs.

Listing 5.26 Enabling the emulator to process multiple instructions

```
1 struct CPU {
     registers: [u8; 16],
     position in memory: usize,
 4
     memory: [u8; 0x1000],
 5 }
 6
 7 impl CPU {
     fn read opcode(&self) -> u16 {
       let p = self.position in memory;
10
       let op byte1 = self.memory[p] as u16;
11
       let op byte2 = self.memory[p + 1] as u16;
12
13
       op_byte1 << 8 | op_byte2
14
                                              Continues execution
15
                                             beyond processing a
16
     fn run(&mut self) {
                                             single instruction
17
      loop {
         let opcode = self.read opcode();
18
19
         self.position_in_memory += 2;
                                                          Increments
20
                                                          position in memory to
         let c = ((opcode & 0xF000) >> 12) as u8;
2.1
                                                          point to the next instruction
22
         let x = ((opcode & 0x0F00) >> 8) as u8;
         let y = ((opcode & 0x00F0) >> 4) as u8;
                                                             Short-circuits the function
         let d = ((opcode & 0x000F) >> 0) as u8;
24
                                                             to terminate execution
25
                                                             when the opcode 0x0000 is
         match (c, x, y, d) {
26
                                                             encountered
              (0, 0, 0, 0) => { return; },
2.7
              (0x8, _{,} , _{,} 0x4) => self.add_xy(x, y),
28
29
                                => todo!("opcode {:04x}", opcode),
3.0
31
32
33
     fn add xy(&mut self, x: u8, y: u8) {
34
       let arg1 = self.registers[x as usize];
35
       let arg2 = self.registers[y as usize];
36
37
       let (val, overflow) = arg1.overflowing add(arg2);
38
39
       self.registers[x as usize] = val;
40
       if overflow {
41
```

```
self.registers[0xF] = 1;
42
43
       } else {
         self.registers[0xF] = 0;
45
46
47 }
48
49 fn main() {
50
    let mut cpu = CPU {
51
     registers: [0; 16],
52
     memory: [0; 4096],
53
      position in memory: 0,
54
55
56
     cpu.registers[0] = 5;
57
     cpu.registers[1] = 10;
     cpu.registers[2] = 10;
58
                                  Initializes a few
                                  registers with values
59
     cpu.registers[3] = 10;
60
                                              Loads opcode 0x8014, which
     let mem = &mut cpu.memory;
61
                                              adds register 1 to register 0
62
     mem[0] = 0x80; mem[1] = 0x14;
63
     mem[2] = 0x80; mem[3] = 0x24;
                                                 Loads opcode 0x8024, which
     mem[4] = 0x80; mem[5] = 0x34;
                                               adds register 2 to register 0
65
66
     cpu.run();
                                               Loads opcode 0x8034. which
67
                                               adds register 3 to register 0
68
     assert eq!(cpu.registers[0], 35);
69
     println!("5 + 10 + 10 + 10 = {}", cpu.registers[0]);
70
71 }
```

When executed, CPU RIA/2 prints its impressive mathematical calculations:

```
5 + 10 + 10 + 10 = 35
```

5.7.4 CPU RIA/3: The Caller

We have nearly built all of the emulator machinery. This section adds the ability for you to call functions. There is no programming language support, however, so any programs still need to be written in binary. In addition to implementing functions, this section validates an assertion made at the start—functions are also data.

EXPANDING THE CPU TO INCLUDE SUPPORT FOR A STACK

To build functions, we need to implement some additional opcodes. These are as follows:

- The CALL opcode (0x2nnn, where nnn is a memory address) sets position_ in memory to nnn, the address of the function.
- The RETURN opcode (0x00EE) sets position_in_memory to the memory address of the previous CALL opcode.

To enable these to opcodes to work together, the CPU needs to have some specialized memory available for storing addresses. This is known as *the stack*. Each CALL opcode

adds an address to the stack by incrementing the stack pointer and writing *nnn* to that position in the stack. Each RETURN opcode removes the top address by decrementing the stack pointer. The following listing, an extract from listing 5.29, provides the details to emulate the CPU.

Listing 5.27 Including a stack and stack pointer

```
1 struct CPU {
2   registers: [u8; 16],
3   position_in_memory: usize,
4   memory: [u8; 4096],
5   stack: [u16; 16],
6   stack_pointer: usize,
7 }
Giving the stack_pointer type usize makes it easier to index values within the stack.
```

DEFINING A FUNCTION AND LOADING IT INTO MEMORY

Within computer science, a function is just a sequence of bytes that can be executed by a CPU.⁴ CPUs start at the first opcode, then make their way to the end. The next few code snippets demonstrate how it is possible to move from a sequence of bytes, then convert that into executable code within CPU RIA/3.

1 Define the function. Our function performs two addition operations and then returns—modest, yet informative. It is three opcodes long. The function's internals look like this in a notation that resembles assembly language:

```
add_twice:
0x8014
0x8014
0x00EE
```

2 Convert opcodes into Rust data types. Translating these three opcodes into Rust's array syntax involves wrapping them in square brackets and using a comma for each number. The function has now become a [u16;3]:

```
let add_twice: [u16;3] = [
    0x8014,
    0x8014,
    0x00EE,
];
```

We want to be able to deal with one byte in the next step, so we'll decompose the [u16;3] array further into a [u8;6] array:

```
let add_twice: [u8;6] = [
   0x80, 0x14,
   0x80, 0x14,
   0x00, 0xEE,
];
```

⁴ The sequence of bytes must also be tagged as executable. The tagging process is explained in section 6.1.4.

3 Load the function into RAM. Assuming that we wish to load that function into memory address 0x100, here are two options. First, if we have our function available as a slice, we can copy it across to memory with the copy_from_slice() method:

```
fn main() {
  let mut memory: [u8; 4096] = [0; 4096];
  let mem = &mut memory;

  let add_twice = [
     0x80, 0x14,
     0x80, 0x14,
     0x00, 0xEE,
  ];

  mem[0x100..0x106].copy_from_slice(&add_twice);

  println!("{:?}", &mem[0x100..0x106]);
  }

  Prints [128, 20,
     128, 20, 0, 238]
```

An alternative approach that achieves the same effect within memory without requiring a temporary array is to overwrite bytes directly:

```
fn main() {
  let mut memory: [u8; 4096] = [0; 4096];
  let mem = &mut memory;

  mem[0x100] = 0x80; mem[0x101] = 0x14;
  mem[0x102] = 0x80; mem[0x103] = 0x14;
  mem[0x104] = 0x00; mem[0x105] = 0xEE;
  println!("{:?}", &mem[0x100..0x106]);
}

    Prints [128, 20, 0, 238]
}
```

The approach taken in the last snippet is exactly what is used within the main() function of lines 96–98 of listing 5.29. Now that we know how to load a function into memory, it's time to learn how to instruct a CPU to actually call it.

IMPLEMENTING THE CALL AND RETURN OPCODES

Calling a function is a three-step process:

- **1** Store the current memory location on the stack.
- 2 Increment the stack pointer.
- 3 Set the current memory location to the intended memory address.

Returning from a function involves reversing the calling process:

- **1** Decrement the stack pointer.
- 2 Retrieve the calling memory address from the stack.
- 3 Set the current memory location to the intended memory address.

Modifies

to affect

self.position

in memory

jumping to

that address

The following listing, an extract from listing 5.29, focuses on the call() and ret() methods.

Listing 5.28 Adding the call() and ret() methods

```
41 fn call(&mut self, addr: u16) {
        let sp = self.stack pointer;
                                                                    Adds the current
43
        let stack = &mut self.stack;
                                                                    position in memory to the
                                                                    stack. This memory address
        if sp > stack.len() {
                                                                    is two bytes higher than the
46
            panic!("Stack overflow!")
                                                                    calling location as it is
47
                                                                    incremented within the body
48
                                                                    of the run() method.
49
        stack[sp] = self.position in memory as u16;
        self.stack pointer += 1;
50
                                                            Increments self.stack pointer to
51
        self.position in memory = addr as usize;
                                                            prevent self.position in memory
52 }
                                                            from being overwritten until it
53
                                                            needs to be accessed again in a
54 fn ret(&mut self) {
                                                            subsequent return
        if self.stack pointer == 0 {
            panic!("Stack underflow");
56
57
58
59
        self.stack pointer -= 1;
        let call addr = self.stack[self.stack pointer];
                                                                    Jumps to the position in
61
        self.position in memory = call addr as usize;
                                                                    memory where an
                                                                     earlier call was made
62 }
```

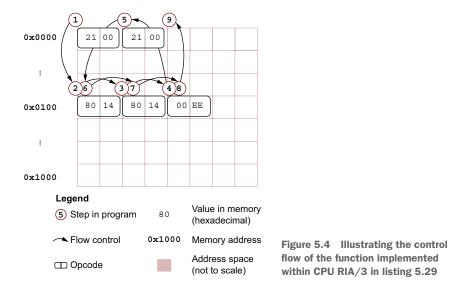

FULL CODE LISTING FOR CPU RIA/3: THE CALLER

Now that we have all of the pieces ready, let's assemble those into a working program. Listing 5.29 is able to compute a (hard-coded) mathematical expression. Here's its output:

```
5 + (10 * 2) + (10 * 2) = 45
```

This calculation is made without the source code that you may be used to. You will need to make do with interpreting hexadecimal numbers. To help, figure 5.4 illustrates what happens within the CPU during cpu.run(). The arrows reflect the state of the cpu.position in memory variable as it makes its way through the program.

Listing 5.29 shows our completed emulator for CPU RIA/3, the Caller. You'll find the source code for this listing in ch5/ch5-cpu3/src/main.rs.

Listing 5.29 Emulating a CPU that incorporates user-defined functions

```
1 struct CPU {
     registers: [u8; 16],
 3
    position in memory: usize,
    memory: [u8; 4096],
 5
    stack: [u16; 16],
 6
     stack pointer: usize,
 7 }
9 impl CPU {
10
    fn read opcode(&self) -> u16 {
11
       let p = self.position in memory;
12
       let op byte1 = self.memory[p] as u16;
       let op_byte2 = self.memory[p + 1] as u16;
13
14
15
      op_byte1 << 8 | op_byte2
16
17
18
     fn run(&mut self) {
19
      loop {
20
         let opcode = self.read opcode();
21
         self.position_in_memory += 2;
22
23
         let c = ((opcode & 0xF000) >> 12) as u8;
24
         let x = ((opcode & 0x0F00) >> 8) as u8;
         let y = ((opcode & 0x00F0) >> 4) as u8;
25
26
         let d = ((opcode & 0x000F) >> 0) as u8;
27
28
         let nnn = opcode & 0x0FFF;
29
         // let kk = (opcode & 0x00FF) as u8;
30
31
         match (c, x, y, d)
```

```
( 0,
32
                     0, 0, 0) => { return; },
33
             ( 0,
                     0, 0xE, 0xE) => self.ret(),
                          _, _) => self.call(nnn),
34

                                                                        register 1's value to register 0
             102
                    assert eq!(cpu.registers[0], 45);
                    println!("5 + (10 * 2) + (10 * 2) = \{\}", cpu.registers[0]);
              103
              104 }
```

As you delve into systems' documentation, you will find that real-life functions are more complicated than simply jumping to a predefined memory location. Operating systems and CPU architectures differ in calling conventions and in their capabilities. Sometimes operands will need to be added to the stack; sometimes they'll need to be inserted into defined registers. Still, while the specific mechanics can differ, the process is roughly similar to what you have just encountered. Congratulations on making it this far.

5.7.5 CPU 4: Adding the rest

With a few extra opcodes, it's possible to implement multiplication and many more functions within your inchoate CPU. Check the source code that comes along with the book, specifically the ch5/ch5-cpu4 directory at https://github.com/rust-in-action/code for a fuller implementation of the CHIP-8 specification.

The last step in learning about CPUs and data is to understand how control flow works. Within CHIP-8, control flow works by comparing values in registers, then modifying position_in_memory, depending on the outcome. There are no while or for loops within a CPU. Creating these in programming languages is the art of the compiler writer.

Summary

- The same bit pattern can represent multiple values, depending on its data type.
- Integer types within Rust's standard library have a fixed width. Attempting to increment past an integer's maximum value is an error called an integer overflow. Decrementing past its lowest value is called integer underflow.
- Compiling programs with optimization enabled (for example, via cargo build
 --release) can expose your programs to integer overflow and underflow as
 run-time checks are disabled.

- Endianness refers to the layout of bytes in multibyte types. Each CPU manufacturer decides the endianness of its chips. A program compiled for a little-endian CPU malfunctions if one attempts to run it on a system with a big-endian CPU.
- Decimal numbers are primarily represented by floating-point number types. The standard that Rust follows for its £32 and £64 types is IEEE 754. These types are also known as single precision and double precision floating point.
- Within f32 and f64 types, identical bit patterns can compare as unequal (e.g., f32::NAN!= f32::NAN), and differing bit patterns can compare as equal (e.g., -0 == 0). Accordingly, f32 and f64 only satisfy a partial equivalence relation. Programmers should be mindful of this when comparing floating-point values for equality.
- Bitwise operations are useful for manipulating the internals of data structures.
 However, doing so can often be highly unsafe.
- Fixed-point number formats are also available. These represent numbers by encoding a value as the nominator and using an implicit denominator.
- Implement std::convert::From when you want to support type conversions. But in cases where the conversion may fail, the std::convert::TryFrom trait is the preferred option.
- A CPU opcode is a number that represents an instruction rather than data.
 Memory addresses are also just numbers. Function calls are just sequences of numbers.

Memory

This chapter covers

- What pointers are and why some are smart
- What the terms stack and heap mean
- How a program views its memory

This chapter provides you with some of the tacit knowledge held by systems programmers about how a computer's memory operates. It aims to be the most accessible guide to pointers and memory management available. You will learn how applications interact with an operating system (OS). Programmers who understand these dynamics can use that knowledge to maximize their programs' performance, while minimizing their memory footprint.

Memory is a shared resource, and the OS is an arbiter. To make its life easier, the OS lies to your program about how much memory is available and where it's located. Revealing the truth behind those lies requires us to work through some prior knowledge. This is the work of the first two sections of the chapter.

Each of the four sections in this chapter builds on the previous one. None of these sections assume that you've encountered the topic before. There is a fairly large body of theory to cover, but all of it is explained by examples.

In this chapter, you'll create your first graphical application. The chapter introduces little new Rust syntax, as the material is quite dense. You'll learn how to construct pointers, how to interact with an OS via its native API, and how to interact with other programs through Rust's foreign function interface.

6.1 Pointers

Pointers are how computers refer to data that isn't immediately accessible. This topic tends to have an aura of mystique to it. That's not necessary. If you've ever read a book's table of contents, then you've used a pointer. Pointers are just numbers that refer to somewhere else.

If you've never encountered systems programming before, there is a lot of terminology to grapple with that describes unfamiliar concepts. Thankfully, though, what's sitting underneath the abstraction is not too difficult to understand. The first thing to grasp is the notation used in this chapter's figures. Figure 6.1 introduces three concepts:

- The arrow refers to some location in memory that is determined at runtime rather than at compile time.
- Each box represents a block of memory, and each block refers to a usize width.
 Other figures use a byte or perhaps even a bit as the chunk of memory these refer to.
- The rounded box underneath the Value label represents three contiguous blocks of memory.

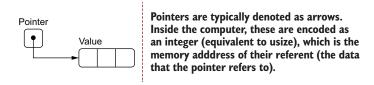

Figure 6.1 Depicting notation used in this chapter's figures for illustrating a pointer. In Rust, pointers are most frequently encountered as &T and &mut T, where T is the type of the value.

For newcomers, pointers are scary and, at the same time, awe-inspiring. Their proper use requires that you know exactly how your program is laid out in memory. Imagine reading a table of contents that says chapter 4 starts on page 97, but it actually starts on page 107. That would be frustrating, but at least you could cope with the mistake.

A computer doesn't experience frustration. It also lacks any intuition that it has pointed to the wrong place. It just keeps working, correctly or incorrectly, as if it had been given the correct location. The fear of pointers is that you will introduce some impossible-to-debug error.

Pointers 177

We can think of data stored within the program's memory as being scattered around somewhere within physical RAM. To make use of that RAM, there needs to be some sort of retrieval system in place. An *address space* is that retrieval system.

Pointers are encoded as memory addresses, which are represented as integers of type usize. An address points to somewhere within the address space. For the moment, think of the address space as all of your RAM laid out end to end in a single line.

Why are memory addresses encoded as usize? Surely there's no 64-bit computer with 2⁶⁴ bytes of RAM. The range of the address space is a façade provided by the OS and the CPU. Programs only know an orderly series of bytes, irrespective of the amount of RAM that is actually available in the system. We discuss how this works later in the virtual memory section of this chapter.

NOTE Another interesting example is the Option<T> type. Rust uses null pointer optimization to ensure that an Option<T> occupies 0 bytes in the compiled binary. The None variant is represented by a *null pointer* (a pointer to invalid memory), allowing the Some (T) variant to have no additional indirection.

What are the differences between references, pointers, and memory addresses?

References, pointers, and memory addresses are confusingly similar:

- A memory address, often shortened to address, is a number that happens to refer to a single byte in memory. Memory addresses are abstractions provided by assembly languages.
- A pointer, sometimes expanded to raw pointer, is a memory address that points to a value of some type. Pointers are abstractions provided by higher-level languages.
- A reference is a pointer, or in the case of dynamically sized types, a pointer and an integer with extra guarantees. References are abstractions provided by Rust.

Compilers are able to determine spans of valid bytes for many types. For example, when a compiler creates a pointer to an i32, it can verify that there are 4 bytes that encode an integer. This is more useful than simply having a memory address, which may or may not point to any valid data type. Unfortunately, the programmer bears the responsibility for ensuring the validity for types with no known size at compile time.

Rust's references offer substantial benefits over pointers:

- References always refer to valid data. Rust's references can only be used when it's legal to access their referent. I'm sure you're familiar with this core tenet of Rust by now!
- References are correctly aligned to multiples of usize. For technical reasons,
 CPUs become quite temperamental when asked to fetch unaligned memory.

(continued)

They operate much more slowly. To mitigate this problem, Rust's types actually include padding bytes so that creating references to these does not slow down your program.

References are able to provide these guarantees for dynamically sized types. For types with no fixed width in memory, Rust ensures that a length is kept alongside the internal pointer. That way Rust can ensure that the program never overruns the type's space in memory.

NOTE The distinguishing characteristic between memory addresses and the two higher abstractions is that the latter two have information about the type of their referent.

6.2 Exploring Rust's reference and pointer types

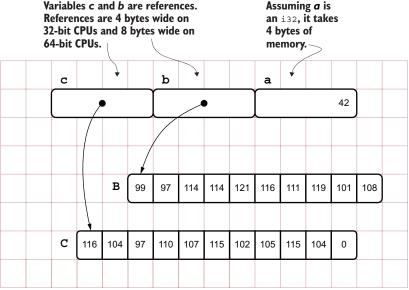

This section teaches you how to work with several of Rust's pointer types. *Rust in Action* tries to stick to the following guidelines when discussing these types:

- References—Signal that the Rust compiler will provide its safety guarantees.
- *Pointers*—Refer to something more primitive. This also includes the implication that we are responsible for maintaining safety. (There is an implied connotation of being unsafe.)
- *Raw pointers*—Used for types where it's important to make their unsafe nature explicit.

Throughout this section, we'll expand on a common code fragment introduced by listing 6.1. Its source code is available in ch6/ch6-pointer-intro.rs. In the listing, two global variables, B and C, are pointed to by references. Those references hold the addresses of B and C, respectively. A view of what's happening follows the code in figures 6.2 and 6.3.

Listing 6.1 Mimicking pointers with references

```
static B: [u8; 10] = [99, 97, 114, 114, 121, 116, 111, 119, 101, 108];
static C: [u8; 11] = [116, 104, 97, 110, 107, 115, 102, 105, 115, 104, 0];
                         For simplicity, uses the same
fn main() {
                                                                   The {:p} syntax asks
                         reference type for this example.
    let a = 42;
                                                                   Rust to format the
                        Later examples distinguish smart
    let b = \&B;
                      pointers from raw pointers and
                                                                   variable as a pointer
    let c = &C;
                                                                   and prints the memory
                        require different types.
                                                                   address that the value
                                                                   points to.
    println!("a: {}, b: {:p}, c: {:p}", a, b, c);
}
```

A partial view of the program's address space

Figure 6.2 An abstract view of how two pointers operate alongside a standard integer. The important lesson here is that the programmer might not know the location of the referent data beforehand.

Listing 6.1 has three variables within its main() function. a is rather trivial; it's just an integer. The other two are more interesting. b and c are references. These refer to two opaque arrays of data, B and C. For the moment, consider Rust references as equivalent to pointers. The output from one execution on a 64-bit machine is as follows:

Figure 6.3 provides a view of the same example in an imaginary address space of 49 bytes. It has a pointer width of two bytes (16 bits). You'll notice that the variables b and c look different in memory, despite being the same type as in listing 6.1. That's due to that because the listing is lying to you. The gritty details and a code example that more closely represents the diagram in figure 6.3 are coming shortly.

As evidenced in figure 6.2, there's one problem with portraying pointers as arrows to disconnected arrays. These tend to de-emphasize that the address space is contiguous and shared between all variables.

For a more thorough examination of what happens under the hood, listing 6.2 produces much more output. It uses more sophisticated types instead of references to

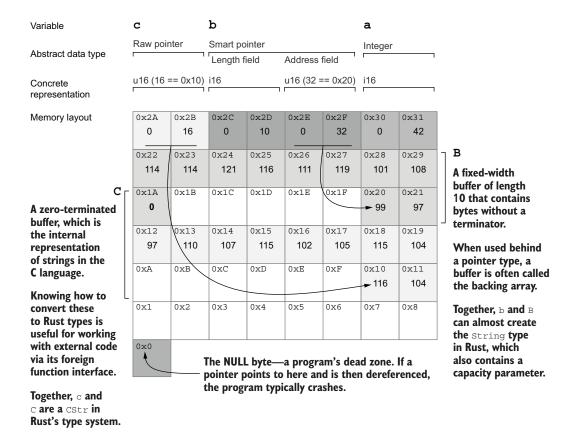

Figure 6.3 An illustrative address space of the program provided in listing 6.1. It provides an illustration of the relationship between addresses (typically written in hexadecimal) and integers (typically written in decimal). White cells represent unused memory.

demonstrate how these differ internally and to correlate more accurately what is presented in figure 6.3. The following shows the output from listing 6.2:

```
(an unsigned integer):
  location: 0x7ffe8f7ddfd0
  size:
            8 bytes
  value:
            42
b (a reference to B):
  location: 0x7ffe8f7ddfd8
             8 bytes
  size:
  points to: 0x55876090c830
c (a "box" for C):
  location: 0x7ffe8f7ddfe0
            16 bytes
  size:
  points to: 0x558762130a40
```

```
B (an array of 10 bytes):
  location: 0x55876090c830
  size:    10 bytes
  value:    [99, 97, 114, 114, 121, 116, 111, 119, 101, 108]

C (an array of 11 bytes):
  location: 0x55876090c83a
  size:    11 bytes
  value:    [116, 104, 97, 110, 107, 115, 102, 105, 115, 104, 0
```

Listing 6.2 Comparing references and Box<T> to several types

&[u8; 10] reads as "a reference to an array of 10 bytes." The array is located in static memory, and the reference itself (a pointer of width usize bytes) is placed on the stack.

```
1 use std::mem::size of;
 3 static B: [u8; 10] = [99, 97, 114, 114, 121, 116, 111, 119, 101, 108];
 4 static C: [u8; 11] = [116, 104, 97, 110, 107, 115, 102, 105, 115, 104, 0];
                                  usize is the memory address size for the
 6 fn main() {
                               CPU the code is compiled for. That CPU is called the compile target.
 7
      let a: usize
                       = 42;
 8
9
      let b: &[u8; 10] = &B;
                                              The Box<[u8]> type is a boxed byte
10
11
      let c: Box<[u8]> = Box::new(C);

    slice. When we place values inside a

                                              box, ownership of the value moves to
12
      13

      println!();
36
37
      println!("C (an array of 11 bytes):");
38
      println!(" location: {:p}", &C);
39
      println!(" size: {:?} bytes", size of::<[u8; 11]>());
40
      println!(" value:
                           {:?}", C);
41 }
```

For readers who are interested in decoding the text within B and C, listing 6.3 is a short program that (almost) creates a memory address layout that resembles figure 6.3 more closely. It contains a number of new Rust features and some relatively arcane syntax, both of which haven't been introduced yet. These will be explained shortly.

Listing 6.3 Printing from strings provided by external sources

```
A smart pointer type that reads from its pointer
                                                  CStr is a C-like string type
        location without needing to copy it first
                                                  that allows Rust to read in
                                                  zero-terminated strings.
   use std::borrow::Cow;
                                                     c char, a type alias for Rust's i8
   use std::ffi::CStr;
                                                     type, presents the possibility of
                                                     a platform-specific nuances.
   use std::os::raw::c char;
   static B: [u8; 10] = [99, 97, 114, 114, 121, 116, 111, 119, 101, 108];
   static C: [u8; 11] = [116, 104, 97, 110, 107, 115, 102, 105, 115, 104, 0];
   fn main() {
                               Introduces each of the variables so that these are accessible
                             from println! later. If we created b and c within the unsafe
      let a = 42;
                             block, these would be out of scope later.
      let b: String;
                                       Cow accepts a type parameter for
                                       the data it points to; str is the type
      let c: Cow<str>;
                                                                                  References cannot be
                                       returned by CStr.to string lossy(),
                                                                                  cast directly to *mut T,
                                       so it is appropriate here.
      unsafe {
                                                                                  the type required by
        let b ptr = &B as *const u8 as *mut u8;
                                                                                  String::from raw parts().
                                                                                  But *const T can be cast
                                                                                  to *mut T, leading to this
        b = String::from raw parts(b ptr, 10, 10);
                                                                                  double cast syntax.
        let c ptr = &C as *const u8 as *const c char;
                                                                                String::from raw parts()
                                                                                accepts a pointer (*mut T)
        c = CStr::from ptr(c ptr).to string lossy();
                                                                                to an array of bytes, a size,
                                                                                and a capacity parameter.
      println!("a: {}, b: {}, c: {}", a, b, c);
                                                                             Converts a *const u8 to a
                                                                             *const i8, aliased to c char.
                                          Conceptually, CStr::from ptr()
String is a smart pointer
                                                                             The conversion to i8 works
                                        takes responsibility for reading
type that holds a pointer to
                                                                             because we remain under 128,
                                          the pointer until it reaches 0;
                                                                            following the ASCII standard.
a backing array and a field
                                           then it generates Cow<str>
to store its size.
                                                       from the result.
```

In listing 6.3, Cow stands for *copy on write*. This smart pointer type is handy when an external source provides a buffer. Avoiding copies increases runtime performance. std::ffi is the foreign function interface module from Rust's standard library. use std::os::raw::c_char; is not strictly needed, but it does make the code's intent clear. C does not define the width of its char type in its standard, although it's one byte wide in practice. Retrieving the type alias c_char from the std::os:raw module allows for differences.

To thoroughly understand the code in listing 6.3, there is quite a bit of ground to cover. We first need to work through what raw pointers are and then discuss a number of feature-rich alternatives that have been built around them.

6.2.1 Raw pointers in Rust

A *raw pointer* is a memory address without Rust's standard guarantees. These are inherently unsafe. For example, unlike references (&T), raw pointers can be null.

If you'll forgive the syntax, raw pointers are denoted as *const T and *mut T for immutable and mutable raw pointers, respectively. Even though each is a single type, these contain three tokens: *, const or mut. Their type, T, a raw pointer to a String, looks like *const String. A raw pointer to an i32 looks like *mut i32. But before we put pointers into practice, here are two other things that are useful to know:

- The difference between a *mut T and a *const T is minimal. These can be freely cast between one another and tend to be used interchangeably, acting as in-source documentation.
- Rust references (&mut T and &T) compile down to raw pointers. That means that it's possible to access the performance of raw pointers without needing to venture into unsafe blocks.

The next listing provides a small example that coerces a reference to a value (&T), creating a raw pointer from an i64 value. It then prints the value and its address in memory via the $\{:p\}$ syntax.

Listing 6.4 Creating a raw pointer (*const T)

```
fn main() {
    let a: i64 = 42;
    let a_ptr = &a as *const i64;

    println!("a: {} ({:p})", a, a_ptr);
}

Casts a reference to the
variable a (&a) to a constant
raw pointer i64 (*const i64)

Prints the value of the variable
a (42) and its address in
memory (0x7ff...)
```

The terms *pointer* and *memory address* are sometimes used interchangeably. These are integers that represent a location in virtual memory. From the compiler's point of view, though, there is one important difference. Rust's pointer types *const T and *mut T always point to the starting byte of T, and these also know the width of type T in bytes. A memory address might refer to anywhere in memory.

An i64 is 8-bytes wide (64 bits ÷ 8 bits per byte). Therefore, if an i64 is stored at address 0x7fffd, then each of the bytes between 0x7ffd..0x8004 must be fetched from RAM to recreate the integer's value. The process of fetching data from RAM from a pointer is known as *dereferencing a pointer*. The following listing identifies a value's address by casting a reference to it as a raw pointer via std::mem::transmute.

Listing 6.5 Identifying a value's address

```
fn main() {
    let a: i64 = 42;
    let a_ptr = &a as *const i64;
    let a_addr: usize = unsafe {
        std::mem::transmute(a_ptr)
    };

    println!("a: {} ({:p}...0x{:x})", a, a_ptr, a_addr + 7);
}
Interprets *const i64 as usize.
Using transmute() is highly unsafe
but is used here to postpone
introducing more syntax.
};
```

Under the hood, references (&T and &mut T) are implemented as raw pointers. These come with extra guarantees and should always be preferred.

WARNING Accessing the value of a raw pointer is always unsafe. Handle with care.

Using raw pointers in Rust code is like working with pyrotechnics. Usually the results are fantastic, sometimes they're painful, and occasionally they're tragic. Raw pointers are often handled in Rust code by the OS or a third-party library.

To demonstrate their volatility, let's work through a quick example with Rust's raw pointers. Creating a pointer of arbitrary types from any integer is perfectly legal. Dereferencing that pointer must occur within an unsafe block, as the following snippet shows. An unsafe block implies that the programmer takes full responsibility for any consequences:

```
fn main() {
    let ptr = 42 as *const Vec<String>;
    unsafe {
        let new_addr = ptr.offset(4);
        println!("{:p} -> {:p}", ptr, new_addr);
    }
}
You can create pointers safely from any integral value. An i32 is not a Vec<String>, but Rust is quite comfortable ignoring that here.
```

To reiterate, raw pointers are not safe. These have a number of properties that mean that their use is strongly discouraged within day-to-day Rust code:

- Raw pointers do not own their values. The Rust compiler does not check that the referent data is still valid when these are accessed.
- Multiple raw pointers to the same data are allowed. Every raw pointer can have write, read-write access to data. This means that there is no time when Rust can guarantee that shared data is valid.

Notwithstanding those warnings, there are a small number of valid reasons to make use of raw pointers:

- It's unavoidable. Perhaps some OS call or third-party code requires a raw pointer.
 Raw pointers are common within C code that provides an external interface.
- Shared access to something is essential and runtime performance is paramount. Perhaps multiple components within your application require equal access to some expensive-to-compute variable. If you're willing to take on the risk of one of those components poisoning every other component with some silly mistake, then raw pointers are an option of last resort.

6.2.2 Rust's pointer ecosystem

Given that raw pointers are unsafe, what is the safer alternative? The alternative is to use smart pointers. In the Rust community, a *smart pointer* is a pointer type that has some kind of superpower, over and above the ability to deference a memory address. You will probably encounter the term *wrapper type* as well. Rust's smart pointer types tend to wrap raw pointers and bestow them with added semantics.

A narrower definition of smart pointer is common in the C communities. There authors (generally) imply that the term smart pointer means the C equivalents of Rust's core::ptr::Unique, core::ptr::Shared, and std::rc::Weak types. We will introduce these types shortly.

NOTE The term *fat pointer* refers to memory layout. Thin pointers, such as raw pointers, are a single usize wide. Fat pointers are usually two usize wide, and occasionally more.

Rust has an extensive set of pointer (and pointer-like) types in its standard library. Each has its own role, strengths, and weaknesses. Given their unique properties, rather than writing these out as a list, let's model these as characters in a card-based role-playing game, as shown in figure 6.4.

Each of the pointer types introduced here are used extensively throughout the book. As such, we'll give these fuller treatment when that's needed. For now, the two novel attributes that appear within the Powers section of some of these cards are interior mutability and shared ownership. These two terms warrant some discussion.

With interior mutability, you may want to provide an argument to a method that takes immutable values, yet you need to retain mutability. If you're willing to pay the runtime performance cost, it's possible to fake immutability. If the method requires an owned value, wrap the argument in Cell<T>. References can also be wrapped in RefCell<T>. It is common when using the reference counted types Rc<T> and Arc<T>, which only accept immutable arguments, to also wrap those in Cell<T> or Ref-Cell<T>. The resulting type might look like Rc<RefCell<T>>. This means that you pay the runtime cost twice but with significantly more flexibility.

With shared ownership, some objects, such as a network connection or, perhaps, access to some OS service, are difficult to mould into the pattern of having a single place with read-write access at any given time. Code might be simplified if two parts of

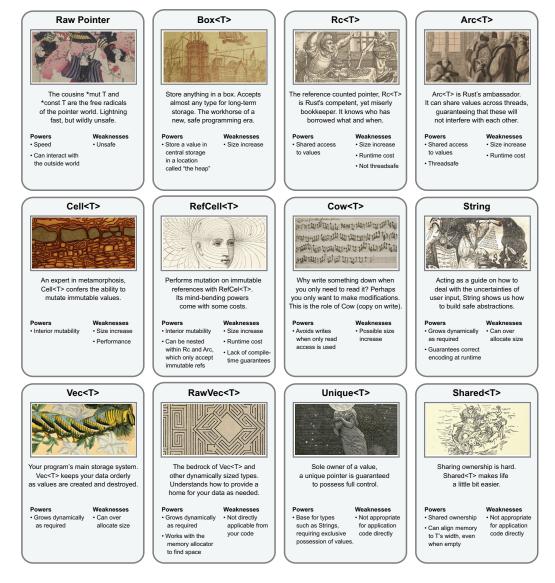

Figure 6.4 A fictitious role-playing card game describing the characteristics of Rust's smart pointer types

the program can share access to that single resource. Rust allows you to do this, but again, at the expense of a runtime cost.

6.2.3 Smart pointer building blocks

You might find yourself in a situation where you want to build your own smart pointer type with its own semantics. Perhaps a new research paper has been released, and you want to incorporate its results into your own work. Perhaps you're conducting the research. Regardless, it might be useful to know that Rust's pointer types are extensible—these are designed with extension in mind.

All of the programmer-facing pointer types like Box<T> are built from more primitive types that live deeper within Rust, often in its core or alloc modules. Additionally, the C++ smart pointer types have Rust counterparts. Here are some useful starting points for you when building your own smart pointer types:

- core::ptr::Unique is the basis for types such as String, Box<T>, and the pointer field Vec<T>.
- core::ptr::Shared is the basis for Rc<T> and Arc<T>, and it can handle situations where shared access is desired.

In addition, the following tools can also be handy in certain situations:

- Deeply interlinked data structures can benefit from std::rc::Weak and std::arc:: Weak for single and multi-threaded programs, respectively. These allow access to data within an Rc/Arc without incrementing its reference count. This can prevent never-ending cycles of pointers.
- The alloc::raw_vec::RawVec type underlies Vec<T> and VecDeq<T>. An expandable, double-ended queue that hasn't appeared in the book so far, it understands how to allocate and deallocate memory in a smart way for any given type.
- The std::cell::UnsafeCell type sits behind both Cell<T> and RefCell<T>. If you would like to provide interior mutability to your types, its implementation is worth investigating.

A full treatment of building new safe pointers touches on some of Rust's internals. These building blocks have their own building blocks. Unfortunately, explaining every detail will diverge too far from our goals for this chapter.

NOTE Inquisitive readers should investigate the source code of the standard library's pointer types. For example, the std::cell::RefCell type is documented at https://doc.rust-lang.org/std/cell/struct.RefCell.html. Clicking the [src] button on that web page directs you to the type's definition.

6.3 Providing programs with memory for their data

This section attempts to demystify the terms *the stack* and *the heap*. These terms often appear in contexts that presuppose you already know what they mean. That isn't the case here. We'll cover the details of what they are, why they exist, and how to make use of that knowledge to make your programs leaner and faster.

Some people hate wading through the details, though. For those readers, here is the salient difference between the stack and the heap:

- The stack is fast.
- The heap is slow.

That difference leads to the following axiom: "When in doubt, prefer the stack." To place data onto the stack, the compiler must know the type's size at compile time.

Translated to Rust, that means, "When in doubt, use types that implement Sized." Now that you've got the gist of those terms, it's time to learn when to take the slow path and how to avoid it when you want to take a faster one.

6.3.1 The stack

The stack is often described by analogy. Think of a stack of dinner plates waiting in the cupboard of a commercial kitchen. Cooks are taking plates off the stack to serve food, and dishwashers are placing new plates on the top.

The unit (the plate) of a computing stack is the stack frame, also known as the *allocation record*. You are probably used to thinking of this as a group of variables and other data. Like many descriptions in computing, the stack and the heap are analogies that only partially fit. Even though the stack is often compared by analogy to a stack of dinner plates waiting in the cupboard, unfortunately, that mental picture is inaccurate. Here are some differences:

- The stack actually contains two levels of objects: stack frames and data.
- The stack grants programmers access to multiple elements stored within it, rather than the top item only.
- The stack can include elements of arbitrary size, where the implication of the dinner plate analogy is that all elements must be of the same size.

So why is the stack called the stack? Because of the usage pattern. Entries on the stack are made in a Last In, First Out (LIFO) manner.

The entries in the stack are called *stack frames*. Stack frames are created as function calls are made. As a program progresses, a cursor within the CPU updates to reflect the current address of the current stack frame. The cursor is known as the *stack pointer*.

As functions are called within functions, the stack pointer decreases in value as the stack grows. When a function returns, the stack pointer increases.

Stack frames contain a function's state during the call. When a function is called within a function, the older function's values are effectively frozen in time. Stack frames are also known as *activation frames*, and less commonly *allocation records*.¹

Unlike dinner plates, every stack frame is a different size. The stack frame contains space for its function's arguments, a pointer to the original call site, and local variables (except the data which is allocated on the heap).

NOTE If you are unfamiliar with what the term *call site* means, see the CPU emulation section in chapter 5.

To understand what is happening more fully, let's consider a thought experiment. Imagine a diligent, yet absurdly single-minded cook in a commercial kitchen. The cook takes each table's docket and places those in a queue. The cook has a fairly bad memory, so each current order is written down a notebook. As new orders come in,

¹ To be precise, the activation frame is called a stack frame when allocated on the stack.

the cook updates the notebook to refer to the new order. When orders are complete, the notebook page is changed to the next item in the queue. Unfortunately, for customers in this restaurant, the book operates in a LIFO manner. Hopefully, you will not be one of the early orders during tomorrow's lunch rush.

In this analogy, the notebook plays the role of the stack pointer. The stack itself is comprised of variable-length dockets, representing stack frames. Like stack frames, restaurant dockets contain some metadata. For example, the table number can act as the return address.

The stack's primary role is to make space for local variables. Why is the stack fast? All of a function's variables are side by side in memory. That speeds up access.

Improving the ergonomics of functions that can only accept String or &str

As a library author, it can simplify downstream application code if your functions can accept both &str and String types. Unfortunately, these two types have different representations in memory. One (&str) is allocated on the stack, the other (String) allocates memory on the heap. That means that types cannot be trivially cast between one another. It's possible, however, to work around this with Rust's generics.

Consider the example of validating a password. For the purposes of the example, a strong password is one that's at least 6 characters long. The following shows how to validate the password by checking its length:

```
fn is_strong(password: String) -> bool {
   password.len() > 5
}
```

is strong can only accept String. That means that the following code won't work:

```
let pw = "justok";
let is strong = is strong(pw);
```

But generic code can help. In cases where read-only access is required, use functions with the type signature $\operatorname{fn} x < T$: $\operatorname{AsRef} < \operatorname{str} >> (a:T)$ rather than $\operatorname{fn} x(a:\operatorname{String})$. The fairly unwieldy type signature reads "as function x takes an argument password of type T, where T implements $\operatorname{AsRef} < \operatorname{str} >$ " Implementors of $\operatorname{AsRef} < \operatorname{str} >$ behave as a reference to str even when these are not.

Here is the code snippet again for the previous listing, accepting any type T that implements AsRef<str>. It now has the new signature in place:

```
fn is_strong<T: AsRef<str>>> (password: T) -> bool {
    password.as_ref().len() > 5
}

Provides a
String or a &str
as password
```

When read-write access to the argument is required, normally you can make use of AsRef<T>'s sibling trait AsMut<T>. Unfortunately for this example, &'static str cannot become mutable and so another strategy can be deployed: implicit conversion.

(continued)

It's possible to ask Rust to accept only those types that can be converted to String. The following example performs that conversion within the function and applies any required business logic to that newly created String. This can circumvent the issue of &str being an immutable value.

```
fn is_strong<T: Into<String>>(password: T) -> bool {
   password.into().len() > 5
}
```

This implicit conversion strategy does have significant risks, though. If a string-ified version of the password variable needs to be created multiple times in the pipeline, it would be much more efficient to require an explicit conversion within the calling application. That way the String would be created once and reused.

6.3.2 The heap

This section introduces the heap. The heap is an area of program memory for types that do not have known sizes at compile time.

What does it mean to have no known size at compile time? In Rust, there are two meanings. Some types grow and shrink over time as required. Obvious cases are String and Vec<T>. Other types are unable to tell the Rust compiler how much memory to allocate even though these don't change size at runtime. These are known as dynamically sized types. Slices ([T]) are the commonly cited example. Slices have no compile-time length. Internally, these are a pointer to some part of an array. But slices actually represent some number of elements within that array.

Another example is a *trait object*, which we've not described in this book so far. Trait objects allow Rust programmers to mimic some features of dynamic languages by allowing multiple types to be wedged into the same container.

WHAT IS THE HEAP?

You will gain a fuller understanding of *what* the heap is once you work through the next section on virtual memory. For now, let's concentrate on what it is *not*. Once those points are clarified, we'll then work our way back toward some form of truth.

The word "heap" implies disorganization. A closer analogy would be warehouse space in some medium-sized business. As deliveries arrive (as variables are created), the warehouse makes space available. As the business carries out its work, those materials are used, and the warehouse space can now be made available for new deliveries. At times, there are gaps and perhaps a bit of clutter. But overall, there is a good sense of order.

Another mistake is that the heap has no relationship to the data structure that is also known as a heap. That data structure is often used to create priority queues. It's an incredibly clever tool in its own right, but right now it's a complete distraction. The heap is not a data structure. It's an area of memory.

Now that those two distinctions are made, let's inch toward an explanation. The critical difference from a usage point of view is that variables on the heap must be accessed via a pointer, whereas this is not required with variables accessed on the stack.

Although it's a trivial example, let's consider two variables, a and b. These both represent the integers 40 and 60, respectively. In one of those cases though, the integer happens to live on the heap, as in this example:

```
let a: i32 = 40;
let b: Box<i32> = Box::new(60);
```

Now, let's demonstrate that critical difference. The following code won't compile:

```
let result = a + b;
```

The boxed value assigned to b is only accessible via a pointer. To access that value, we need to dereference it. The dereference operator is a unary *, which prefixes the variable name:

```
let result = a + *b;
```

This syntax can be difficult to follow at first because the symbol is also used for multiplication. It does, however, become more natural over time. The following listing shows a complete example where creating variables on the heap implies constructing that variable via a pointer type such as Box<T>.

Listing 6.6 Creating variables on the heap

```
fn main() {
    let a: i32 = 40;
    let b: Box<i32> = Box::new(60);

    println!("{} + {} = {}", a, b, a + *b);
}

    To access 60, we need to dereference it.
```

To get a feel for what the heap is and what is happening within memory as a program runs, let's consider a tiny example. In this example, all we will do is to create some numbers on the heap and then add their values together. When run, the program in listing 6.7 produces some fairly trivial output: two 3s. Still, it's really the internals of the program's memory that are important here, not its results.

The code for the next listing is in the file ch6/ch6-heap-via-box/src/main.rs. A pictorial view of the program's memory as it runs (figure 6.5) follows the code. Let's first look at the program's output:

3 3

Listing 6.7 Allocating and deallocating memory on the heap via Box<T>

```
1 use std::mem::drop;
                                     Brings manual drop()
 2
                                     into local scope
 3 fn main() {
 4
        let a = Box::new(1);
                                       Allocates values
        let b = Box::new(1);
                                       on the heap
        let c = Box::new(1);
 6
 7
 8
        let result1 = *a + *b + *c;
                                                         The unary *, the dereference operator.
 9
                                                         returns the value within the box, and
1.0
       drop(a);
                                                         resultI holds the value 3.
        let d = Box::new(1);
11
        let result2 = *b + *c + *d;
12
                                                      Invokes drop(), freeing
13
                                                      memory for other uses
        println!("{} {}", result1, result2);
14
15 }
```

Listing 6.7 places four values on the heap and removes one. It contains some new or, at least, less familiar syntax that might be worthwhile to cover and/or recap:

Box::new(T) allocates T on the heap. Box is a term that can be deceptive if you don't share its intuition.

Something that has been *boxed* lives on the heap, with a pointer to it on the stack. This is demonstrated in the first column of figure 6.5, where the number 0x100 at address 0xfff points to the value 1 at address 0x100. However, no actual box of bytes encloses a value, nor is the value hidden or concealed in some way.

std::mem::drop brings the function drop() into local scope. drop() deletes objects before their scope ends.

Types that implement Drop have a drop() method, but explicitly calling it is illegal within user code. std::mem::drop is an escape hatch from that rule.

Asterisks next to variables (*a, *b, *c, and *d) are unary operators. This is the dereference operator. Dereferencing a Box::(T) returns T. In our case, the variables a, b, c, and d are references that refer to integers.

In figure 6.5, each column illustrates what happens inside memory at 6 lines of code. The stack appears as the boxes along the top, and the heap appears along the bottom. The figure omits several details, but it should help you gain an intuition about the relationship between the stack and the heap.

NOTE If you have experience with a debugger and want to explore what is happening, be sure to compile your code with no optimizations. Compile your code with cargo build (or cargo run) rather than cargo build --release. Using the --release flag actually ends up optimizing all the allocations and arithmetic. If you are invoking rustc manually, use the command rustc --codegen opt-level=0.

Program execution over time

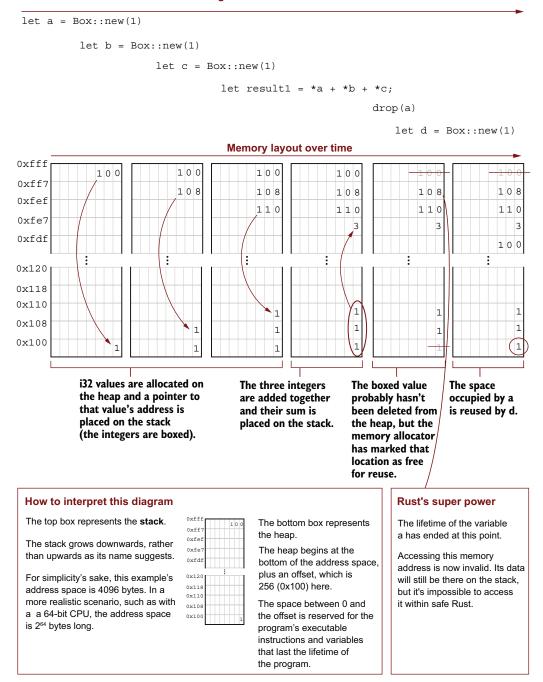

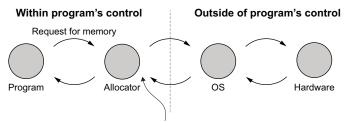

Figure 6.5 A view into a program's memory layout during the execution of listing 6.7

6.3.3 What is dynamic memory allocation?

At any given time, a running program has a fixed number of bytes with which to get its work done. When the program would like more memory, it needs to ask for more from the OS. This is known as *dynamic memory allocation* and is shown in figure 6.6. Dynamic memory allocation is a three-step process:

- 1 Request memory from the OS via a system call. In the UNIX family of operating systems, this system call is alloc(). In MS Windows, the call is HeapAlloc().
- 2 Make use of the allocated memory in the program.
- 3 Release memory that isn't needed back to the OS via free() for UNIX systems and HeapFree() for Windows.

Smart bookkeeping by the allocator can avoid lots of extra work by the operating system and the computer's hardware.

Figure 6.6 Conceptual view of dynamic memory allocation. Requests for memory originate and terminate at the program level but involve several other components. At each stage, the components may short-circuit the process and return quickly.

As it turns out, there is an intermediary between the program and the OS: the *allocator*, a specialist subprogram that is embedded in your program behind the scenes. It will often perform optimizations that avoid lots of work within the OS and CPU.

Let's examine the performance impact of dynamic memory allocation and strategies to reduce that impact. Before starting, let's recap why there's a performance difference between the stack and the heap. Remember that the stack and the heap are conceptual abstractions only. These do not exist as physical partitions of your computer's memory. What accounts for their different performance characteristics?

Accessing data on the stack is fast because a function's local variables, which are allocated on the stack, reside next to each other in RAM. This is sometimes referred to as a *contiguous layout*.

A contiguous layout is cache-friendly. Alternatively, variables allocated on the heap are unlikely to reside next to each other. Moreover, accessing data on the heap involves dereferencing the pointer. That implies a page table lookup and a trip to main memory. Table 6.1 summarizes these differences.

Table 6.1	A simplistic,	yet	practical	table	for	comparing t	he
stack and the heap							

Stack	Неар
Simple	Complex
Safe	Dangerous*
Fast	Slow
Rigid	Flexible

^{*} Not in safe Rust!

There is a trade-off for the stack's increased speed. Data structures on the stack must stay the same size during the lifetime of the program. Data structures allocated on the heap are more flexible. Because these are accessed via a pointer, that pointer can be changed.

To quantify this impact, we need to learn how to measure the cost. To get a large number of measurements, we need a program that creates and destroys many values. Let's create a toy program. Figure 6.7 shows show a background element to a video game.

Figure 6.7 Screenshots from the result of running listing 6.9

After running listing 6.9, you should see a window appear on your screen filled with a dark grey background. White snow-like dots will start to float from the bottom and fade as they approach the top. If you check the console output, streams of numbers will appear. Their significance will be explained once we discuss the code. Listing 6.9 contains three major sections:

- A memory allocator (the ReportingAllocator struct) records the time that dynamic memory allocations take.
- Definitions of the structs World and Particle and how these behave over time.
- The main() function deals with window creation and initialization.

The following listing shows the dependencies for our toy program (listing 6.9). The source for the following listing is in ch6/ch6-particles/Cargo.toml. The source for listing 6.9 is in ch6/ch6-particles/main.rs.

138
139
         }
```

```
self.current turn += 1;
140
141
142 }
143
144 fn main() {
145 let (width, height) = (1280.0, 960.0);
146  let mut window: PistonWindow = WindowSettings::new(
147
      "particles", [width, height]
148
149
    .exit on esc(true)
150
    .build()
151
     .expect("Could not create a window.");
152
153
     let mut world = World::new(width, height);
154
     world.add shapes(1000);
155
     while let Some(event) = window.next() {
156
157
      world.update();
158
159
      window.draw_2d(&event, |ctx, renderer, _device| {
160
        clear([0.15, 0.17, 0.17, 0.9], renderer);
161
162
        for s in &mut world.particles {
163
           let size = [s.position[0], s.position[1], s.width, s.height];
           rectangle(s.color, size, ctx.transform, renderer);
164
165
166
      });
    }
167
168 }
```

Listing 6.9 is a fairly long code example, but hopefully, it does not contain any code that's too alien compared to what you've already seen. Toward the end, the code example introduces Rust's closure syntax. If you look at the call to window.draw_2d(), it has a second argument with vertical bars surrounding two variable names (|ctx, renderer, _device| { ... }). Those vertical bars provide space for the closure's arguments, and the curly braces are its body.

A *closure* is a function that is defined in line and can access variables from its surrounding scope. These are often called *anonymous* or *lambda* functions.

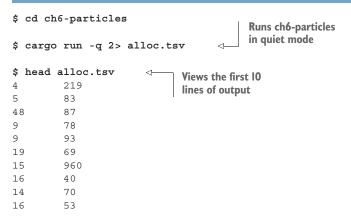

Closures are a common feature within idiomatic Rust code, but this book tends to avoid those where possible to keep examples approachable to programmers from an imperative or object-oriented background. Closures are explained fully in chapter 11. In the interim, it's sufficient to say that these are a convenient shorthand for defining functions. Let's next focus on generating some evidence that allocating variables on the heap (many millions of times) can have a performance impact on your code.

6.3.4 Analyzing the impact of dynamic memory allocation

If you run listing 6.9 from a terminal window, you'll soon see two columns of numbers filling it up. These columns represent the number of bytes allocated, and the duration in nanoseconds taken to fulfil the request. That output can be sent to a file for further

analysis, as shown in the following listing, which redirects stderr from ch6-particles to a file.

Listing 6.10 Creating a report of memory allocations

One interesting aspect from this short extract is that memory allocation speed is not well-correlated with allocation size. When every heap allocation is plotted, this becomes even clearer as figure 6.8 shows.

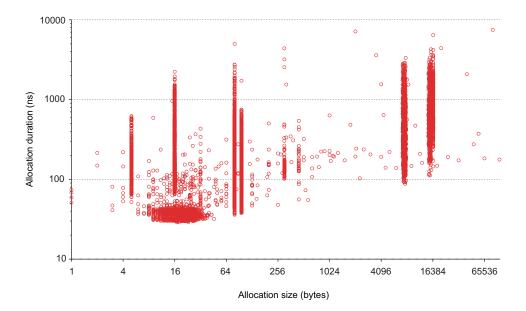

Figure 6.8 Plotting heap allocation times against allocation size shows that there is no clear relationship between the two. The time taken to allocate memory is essentially unpredictable, even when requesting the same amount of memory multiple times.

To generate your own version of figure 6.8, the following listing shows a gnuplot script that can be tweaked as desired. You'll find this source in the file ch6/alloc.plot.

Listing 6.11 Script used to generate figure 6.8 with gnuplot

```
set key off
set rmargin 5
set grid ytics noxtics nocbtics back
set border 3 back lw 2 lc rgbcolor "#222222"
set xlabel "Allocation size (bytes)"
set logscale x 2
set xtics nomirror out
set xrange [0 to 100000]
set ylabel "Allocation duration (ns)"
set logscale y
set yrange [10 to 10000]
set ytics nomirror out
plot "alloc.tsv" with points \
   pointtype 6 \
    pointsize 1.25 \
    linecolor rgbcolor "#22dd3131"
```

Although larger memory allocations do tend to take longer than shorter ones, it's not guaranteed. The range of durations for allocating memory of the same number is over an order of magnitude. It might take 100 nanoseconds; it might take 1,000.

Does it matter? Probably not. But it might. If you have a 3 GHz CPU, then your processor is capable of performing 3 billion operations per second. If there is a 100 nanosecond delay between each of those operations, your computer can only perform 30 million operations in the same time frame. Perhaps those hundreds of microseconds really do count for your application. Some general strategies for minimizing heap allocations include

- Using arrays of uninitialized objects. Instead of creating objects from scratch as required, create a bulk lot of those with zeroed values. When the time comes to activate one of those objects, set its values to non-zero. This can be a very dangerous strategy because you're circumventing Rust's lifetime checks.
- Using an allocator that is tuned for your application's access memory profile. Memory allocators are often sensitive to the sizes where these perform best.
- Investigate arena::Arena and arena::TypedArena. These allow objects to be created on the fly, but alloc() and free() are only called when the arena is created and destroyed.

6.4 Virtual memory

This section explains what the term virtual memory means and why it exists. You will be able to use this knowledge to speed up your programs by building software that goes with the grain. CPUs can compute faster when they're able to access memory quickly. Understanding some of the dynamics of the computer architecture can help to provide CPUs with memory efficiently.

6.4.1 Background

I have spent far too much of my life playing computer games. As enjoyable and challenging as I've found these, I've often wondered about whether I would have been better off spending my teenage years doing something more productive. Still, it's left me with plenty of memories. But some of those memories still leave a bitter taste.

Occasionally, someone would enter the game and obliterate everyone with near perfect aim and seemingly impossibly high health ratings. Other players would decry, "Cheater!" but were more or less helpless in defeat. While waiting in in-game purgatory, I would sit wondering, "How is that possible? How are those tweaks to the game actually made?"

By working through this section's examples, you would have built the core of a tool that's capable of inspecting and modifying values of a running program.

Terms related to virtual memory

Terminology within this area is particularly arcane. It is often tied to decisions made many decades ago when the earliest computers were being designed. Here is a quick reference to some of the most important terms:

- Page—A fixed-size block of words of real memory. Typically 4 KB in size for 64-bit operating systems.
- Word—Any type that is size of a pointer. This corresponds to the width of the CPU's registers. In Rust, usize and isize are word-length types.
- Page fault—An error raised by the CPU when a valid memory address is requested that is not currently in physical RAM. This signals to the OS that at least one page must be swapped back into memory.
- Swapping—Migrating a page of memory stored temporarily on disk from main memory upon request.
- Virtual memory—The program's view of its memory. All data accessible to a program is provided in its address space by the OS.
- Real memory—The operating system's view of the physical memory available
 on the system. In many technical texts, real memory is defined independently
 from physical memory, which becomes much more of an electrical engineering term.
- Page table—The data structure maintained by the OS to manage translating from virtual to real memory.

Virtual memory 203

 Segment—A block within virtual memory. Virtual memory is divided into blocks to minimize the space required to translate between virtual and physical addresses.

- Segmentation fault—An error raised by the CPU when an illegal memory address is requested.
- MMU—A component of the CPU that manages memory address translation.
 Maintains a cache of recently translated addresses (called the TLB), which stands for the translation lookaside buffer, although that terminology has fallen from fashion.

One term that has not been defined in any technical sense so far in this book is process. If you've encountered it before and have been wondering why it has been omitted, it will be introduced properly when we talk about concurrency. For now, consider the terms process and its peer operating system process to refer to a running program.

6.4.2 Step 1: Having a process scan its own memory

Intuitively, a program's memory is a series of bytes that starts at location 0 and ends at location n. If a program reports 100 KB of RAM usage, it would seem that n would be somewhere near 100,000. Let's test that intuition.

We'll create a small command-line program that looks through memory, starting at location 0 and ending at 10,000. As it's a small program, it shouldn't occupy more than 10,000 bytes. But when executed, the program will not perform as intended. Sadly, it will crash. You'll learn why the crash occurs as you follow through this section.

Listing 6.12 shows the command-line program. You can find its source in ch6/ch6-memscan-1/src/main.rs. The listing scans through a running program's memory byte by byte, starting at 0. It introduces the syntax for creating raw pointers and dereferencing (reading) those.

Listing 6.12 Attempting to scan a running program's memory byte by byte

```
Converts i to a *const T, a raw pointer
 1 fn main() {
                                                           of type u8 to inspect raw memory
       let mut n nonzero = 0;
 2
                                                           addresses. We treat every address as
 3
                                                           a unit, ignoring the fact that most
        for i in 0..10000 {
 4
                                                           values span multiple bytes.
            let ptr = i as *const u8;
 5
            let byte_at_addr = unsafe { *ptr };
 6
                                                                  Dereferences the pointer, it
 7
                                                                  reads the value at address i.
 8
            if byte at addr != 0 {
                                                                  Another way of saying this
 9
                n nonzero += 1;
                                                                  is "read the value being
1.0
            }
                                                                  pointed to."
11
12
13
        println!("non-zero bytes in memory: {}", n nonzero);
14 }
```

Listing 6.12 crashes because it is attempting to dereference a NULL pointer. When i equals 0, ptr can't really be dereferenced. Incidentally, this is why all raw pointer dereferences must occur within an unsafe block.

How about we attempt to start from a non-zero memory address? Given that the program is executable code, there should be at least several thousand bytes of non-zero data to iterate through. The following listing scans the process's memory starting from 1 to avoid dereferencing a NULL pointer.

Listing 6.13 Scanning a process's memory

```
1 fn main() {
                                    Starts at 1 rather
      let mut n nonzero = 0;
                                   than 0 to avoid a NULL
 3
                                   pointer exception
      4
 5
        let ptr = i as *const u8;
          let byte_at_addr = unsafe { *ptr };
 6
 7
          if byte at addr != 0 {
 9
              n nonzero += 1;
10
      }
11
12
13
      println!("non-zero bytes in memory: {}", n nonzero);
14 }
```

This unfortunately does not completely solve the issue. Listing 6.13 still crashes upon execution, and the number of non-zero bytes is never printed to the console. This is due to what's known as a *segmentation fault*.

Segmentation faults are generated when the CPU and OS detect that your program is attempting to access memory regions that they aren't entitled to. Memory regions are divided into segments. That explains the name.

Let's try a different approach. Rather than attempting to scan through bytes, let's look for the addresses of things that we know exist. We've spent lots of time learning about pointers, so let's put that to use. Listing 6.14 creates several values, examining their addresses.

Every run of listing 6.14 may generate unique values. Here is the output of one run:

```
GLOBAL: 0x7ff6d6ec9310
local_str: 0x7ff6d6ec9314
local_int: 0x23d492f91c
boxed_int: 0x18361b78320
boxed_str: 0x18361b78070
fn int: 0x23d492f8ec
```

As you can see, values appear to be scattered across a wide range. So despite your program (hopefully) only needing a few kilobytes of RAM, a few variables live in giant locations. These are *virtual addresses*.

Virtual memory 205

As explained in the heap versus stack section, the stack starts at the top of the address space and the heap starts near the bottom. In this run, the highest value is 0x7ff6d6ec9314. That's approximately $2^{64} \div 2$. That number is due to the OS reserving half of the address space for itself.

The following listing returns the address of several variables within a program to examine its address space. The source for this listing in ch6/ch6-memscan-3/src/main.rs.

Listing 6.14 Printing the address of variables within a program

```
static GLOBAL: i32 = 1000;
                                         Creates a global static, which is a
                                         global variable in Rust programs
fn noop() -> *const i32 {
    let noop local = 12345;
                                                Creates a global static, which is a
    &noop local as *const i32
                                                global variable in Rust programs
}
                                              Creates a local variable within noop() so that
fn main() {
                                              something outside of main() has a memory address
    let local str = "a";
    let local int = 123;
                                          Creates various values of
    let boxed str = Box::new('b');
                                          several types including
    let boxed int = Box::new(789);
                                          values on the heap
    let fn_int = noop();
    println!("GLOBAL: {:p}", &GLOBAL as *const i32);
    println!("local str: {:p}", local str as *const str);
    println!("local_int: {:p}", &local_int as *const i32);
    println!("boxed int: {:p}", Box::into raw(boxed int));
    println!("boxed_str: {:p}", Box::into_raw(boxed_str));
    println!("fn int: {:p}", fn int);}
```

By now, you should be pretty good at accessing addresses of stored values. There are actually two small lessons that you may have also picked up on:

- *Some memory addresses are illegal.* The OS will shut your program down if it attempts to access memory that is out of bounds.
- Memory addresses are not arbitrary. Although values seem to be spread quite far apart within the address space, values are clustered together within pockets.

Before pressing on with the cheat program, let's step back and look at the system that's operating behind the scenes to translate these virtual addresses to real memory.

6.4.3 Translating virtual addresses to physical addresses

Accessing data in a program requires virtual addresses—the only addresses that the program itself has access to. These get translated into physical addresses. This process involves a dance between the program, the OS, the CPU, the RAM hardware, and occasionally hard drives and other devices. The CPU is responsible for performing this translation, but the OS stores the instructions.

CPUs contain a *memory management unit* (MMU) that is designed for this one job. For every running program, every virtual address is mapped to a physical address. Those instructions are stored at a predefined address in memory as well. That means, in the worst case, every attempt at accessing memory addresses incurs two memory lookups. But it's possible to avoid the worst case.

The CPU maintains a cache of recently translated addresses. It has its own (fast) memory to speed up accessing memory. For historic reasons, this cache is known as the *translation lookaside buffer*, often abbreviated as TLB. Programmers optimizing for performance need to keep data structures lean and avoid deeply nested structures. Reaching the capacity of the TLB (typically around 100 pages for x86 processors) can be costly.

Looking into how the translation system operates reveals more, often quite complex, details. Virtual addresses are grouped into blocks called *pages*, which are typically 4 KB in size. This practice avoids the need to store a translation mapping for every single variable in every program. Having a uniform size for each page also assists in avoiding a phenomenon known as *memory fragmentation*, where pockets of empty, yet unusable, space appear within available RAM.

NOTE This is a general guide only. The details of how the OS and CPU cooperate to manage memory differs significantly in some environments. In particular, constrained environments such as microcontrollers can use real addressing. For those interested in learning more, the research field is known as *computer architecture*.

The OS and CPU can play some interesting tricks when data lives within pages of virtual memory. For example

- Having a virtual address space allows the OS to overallocate. Programs that ask
 for more memory than the machine can physically provide are able to be
 accommodated.
- Inactive memory pages can be swapped to disk in a byte-for-byte manner until it's requested by the active program. Swapping is often used during periods of high contention for memory but can be used more generally, depending on an operating system's whims.
- Other size optimizations such as compression can be performed. A program sees its memory intact. Behind the scenes, the OS compresses the program's wasteful data usage.
- Programs are able to share data quickly. If your program requests a large block of zeroes, say, for a newly created array, the OS might point you towards a page filled with zeroes that is currently being used by three other programs. None of the programs are aware that the others are looking at the same physical memory, and the zeroes have different positions within their virtual address space.

Paging can speed up the loading of shared libraries. As a special case of the previous point, if a shared library is already loaded by another program, the OS can avoid loading it into memory twice by pointing the new program to the old data.

Paging adds security between programs. As you discovered earlier in this section, some parts of the address space are illegal to access. The OS has other attributes that it can add. If an attempt is made to write to a read-only page, the OS terminates the program.

Making effective use of the virtual memory system in day-to-day programs requires thinking about how data is represented in RAM. Here are some guidelines:

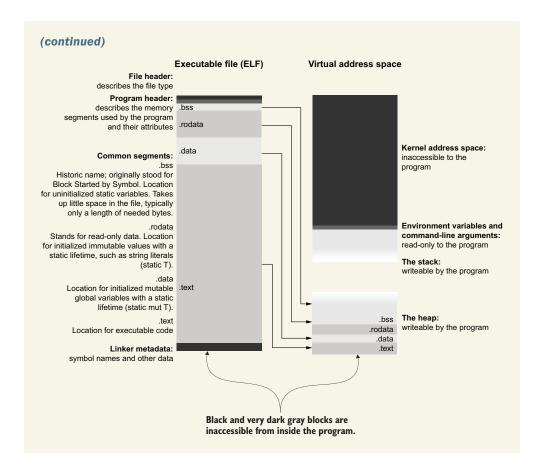

- Keep hot working portions of your program within 4 KB of size. This maintains fast lookups.
- If 4 KB is unreasonable for your application, then the next target to keep under is 4 KB * 100. That rough guide should mean that the CPU can maintain its translation cache (the TLB) in good order to support your program.
- Avoid deeply nested data structures with pointer spaghetti. If a pointer points to another page, then performance suffers.
- *Test the ordering of your nested loops*. CPUs read small blocks of bytes, known as a *cache line*, from the RAM hardware. When processing an array, you can take advantage of this by investigating whether you are doing column-wise or rowwise operations.

One thing to note: virtualization makes this situation worse. If you're running an app inside a virtual machine, the hypervisor must also translate addresses for its guest operating systems. This is why many CPUs ship with virtualization support, which can reduce this extra overhead. Running containers within virtual machines adds another layer of indirection and, therefore, latency. For bare-metal performance, run apps on bare metal.

How does an executable file turn into a program's virtual address space?

The layout of executable files (aka binaries) has many similarities to the address space diagram that we saw earlier in the heap versus stack section of the chapter.

While the exact process is dependent on the OS and file format, the following figure shows a representative example. Each of the segments of the address space that we have discussed are described by binary files. When the executable is started, the OS loads the right bytes into the right places. Once the virtual address space is created, the CPU can be told to jump to the start of the .text segment, and the program begins executing.

6.4.4 Step 2: Working with the OS to scan an address space

Our task is to scan our program's memory while it's running. As we've discovered, the OS maintains the instructions for mapping between a virtual address and a physical address. Can we ask the OS to tell us what is happening?

Operating systems provide an interface for programs to be able to make requests; this is known as a *system call*. Within Windows, the KERNEL.DLL provides the necessary functionality to inspect and manipulate the memory of a running process.

NOTE Why Windows? Well, many Rust programmers use MS Windows as a platform. Also, its functions are well named and don't require as much prior knowledge as the POSIX API.

When you run listing 6.16, you should see lots of output with many sections. This may be similar to the following:

```
MEMORY_BASIC_INFORMATION {

BaseAddress: 0x00007ffbe8d9b000,

Within the Windows API.
```

Virtual memory 209

```
AllocationBase: 0x0000000000000000,
    AllocationProtect: 0,
                                             These fields are the integer representations
    RegionSize: 17568124928,
                                             of enums defined in the Windows API. It's
    State: 65536,
                                             possible to decode these to the enum
    Protect: 1,
                                             variant names, but this isn't available
    Type: 0
                                             without adding extra code to the listing.
MEMORY BASIC INFORMATION {
    BaseAddress: 0x00007ffffffe0000,
    AllocationBase: 0x00007ffffffe0000,
    AllocationProtect: 2,
    RegionSize: 65536,
    State: 8192,
    Protect: 1,
    Type: 131072
```

The following listing shows the dependencies for listing 6.16. You can find its source in ch6/ch6-meminfo-win/Cargo.toml.

Listing 6.15 Dependencies for listing 6.16

```
[package]
name = "meminfo"
version = "0.1.0"
authors = ["Tim McNamara <author@rustinaction.com>"]
edition = "2018"

[dependencies]
winapi = "0.2" #
kernel32-sys = "0.2" #

Provides interaction
with KERNEL.DLL from
the Windows API
```

The following listing shows how to inspect memory via the Windows API. The source code for this listing is in ch6/ch6-meminfo-win/src/main.rs.

Listing 6.16 Inspecting a program's memory

```
use kernel32;
                                          In Rust,
                                                          Pointer types for various internal APIs
                use winapi:
                                          this would
                                                          without an associated type. In Rust,
                                          be a u32.
                                                          std::os::raw::c void defines void pointers;
                use winapi::{
                                                          a HANDLE is a pointer to some opaque
                    DWORD,
                                                          resource within Windows.
                     HANDLE,
   u64 is the
                     LPVOID,
                                                             In Windows, data type names are often prefixed
 usize on this
                     PVOID,
                                                             with a shorthand for their type. P stands for
    machine.
                    SIZE T,
                                                             pointer; LP stands for long pointer (e.g., 64 bit).
                   LPSYSTEM INFO,
A pointer to a
                     SYSTEM INFO,
                                                                         Some structs defined by
SYSTEM INFO
                     MEMORY BASIC INFORMATION as MEMINFO,
                                                                        Windows internally
       struct
                };
```

```
fn main() {
                    let this pid: DWORD;
                    let this proc: HANDLE;
                                                                          Initializes these variables
                    let min addr: LPVOID;
                                                                          from within unsafe blocks.
                                                                          To make these accessible in
                    let max addr: LPVOID;
                                                                           the outer scope, these need
                    let mut base addr: PVOID;
                                                                           to be defined here.
                    let mut proc info: SYSTEM INFO;
                    let mut mem info: MEMORY BASIC INFORMATION;
                    const MEMINFO SIZE: usize = std::mem::size of::<MEMINFO>();
                    unsafe {
                                                                     This block guarantees that
                        base addr = std::mem::zeroed();
                                                                    all memory is initialized.
                         proc info = std::mem::zeroed();
                        mem info = std::mem::zeroed();
 Rather than use a
 return value, this
                                                                     This block of code is where
   function makes
                                                                    system calls are made.
                    unsafe {
use of a C idiom to
                         this pid = kernel32::GetCurrentProcessId();
 provide its result
                         this_proc = kernel32::GetCurrentProcess();
 to the caller. We
                         kernel32::GetSystemInfo(
 provide a pointer
                           &mut proc info as LPSYSTEM INFO
to some predefined
 struct, then read
                    };
 that struct's new
   values once the
                    min_addr = proc_info.lpMinimumApplicationAddress;
                                                                                  Renaming these variables
function returns to
   see the results.
                    max addr = proc info.lpMaximumApplicationAddress;
                                                                                  for convenience
                    println!("{:?} @ {:p}", this_pid, this_proc);
                    println!("{:?}", proc info);
                    println!("min: {:p}, max: {:p}", min addr, max addr);
                                                            This loop does the work
                                                            of scanning through the
                    loop {
                                                            address space.
                         let rc: SIZE T = unsafe {
                             kernel32::VirtualQueryEx(
             Provides
                                                         this proc, base addr,
     information about
                                                         &mut mem info, MEMINFO SIZE as SIZE T)
     a specific segment
                         };
         of the running
            program's
                         if rc == 0 {
       memory address
                             break
        space, starting
          at base_addr
                         println!("{:#?}", mem info);
                         base addr = ((base addr as u64) + mem info.RegionSize) as PVOID;
               }
```

Finally, we have been able to explore an address space without the OS killing our program. Now the question remains: How do we inspect individual variables and modify those?

Summary 211

6.4.5 Step 3: Reading from and writing to process memory

Operating systems provide tools to read and write memory, even in other programs. This is essential for Just-In-Time compilers (JITs), debuggers, and programs to help people "cheat" at games. On Windows, the general process looks something like this in Rust-like pseudocode:

```
let pid = some_process_id;
OpenProcess(pid);
loop address space {
    *call* VirtualQueryEx() to access the next memory segment
    *scan* the segment by calling ReadProcessMemory(),
    looking for a selected pattern

    *call* WriteProcessMemory() with the desired value
}
```

Linux provides an even simpler API via process_vm_readv() and process_vm_writev(). These are analogous to ReadProcessMemory() and WriteProcessMemory() in Windows.

Memory management is a complicated area with many levels of abstraction to uncover. This chapter has tried to focus on those elements that are most salient to your work as a programmer. Now, when you read your next blog post on some low-level coding technique, you should be able to follow along with the terminology.

Summary

- Pointers, references, and memory addresses are identical from the CPU's perspective, but these are significantly different at the programming language level.
- Strings and many other data structures are implemented with a backing array pointed to by a pointer.
- The term *smart pointer* refers to data structures that behave like pointers but have additional capabilities. These almost always incur a space overhead. Additionally, data can include integer length and capacity fields or things that are more sophisticated, such as locks.
- Rust has a rich collection of smart pointer types. Types with more features typically incur greater runtime costs.
- The standard library's smart pointer types are built from building blocks that you can also use to define your own smart pointers if required.
- The heap and the stack are abstractions provided by operating systems and programming languages. These do not exist at the level of the CPU.
- Operating systems often provide mechanisms such as memory allocations to inspect a program's behavior.

Files and storage

This chapter covers

- Learning how data is represented on physical storage devices
- Writing data structures to your preferred file format
- Building a tool to read from a file and inspect its contents
- Creating a working key-value store that's immune from corruption

Storing data permanently on digital media is trickier than it looks. This chapter takes you though some of the details. To transfer information held by ephemeral electrical charges in RAM to (semi)permanent storage media and then be able to retrieve it again later takes several layers of software indirection.

The chapter introduces some new concepts such as how to structure projects into library crates for Rust developers. This task is needed because one of the projects is ambitious. By the end of the chapter, you'll have built a working key-value store that's guaranteed to be durable to hardware failure at any stage. During the chapter, we'll work through a small number of side quests. For example, we implement parity

bit checking and explore what it means to hash a value. To start with, however, let's see if we can create patterns from the raw byte sequence within files.

7.1 What is a file format?

File formats are standards for working with data as an single, ordered sequence of bytes. Storage media like hard disk drives work faster when reading or writing large blocks of data in serial. This contrasts with in-memory data structures, where data layout has less of an impact.

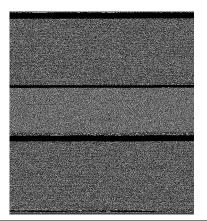

File formats live in a large design space with trade-offs in performance, humanreadability, and portability. Some formats are highly portable and self-describing. Others restrict themselves to being accessible within a single environment and are unable to be read by third-party tools, yet they are high performance.

Table 7.1 illustrates some of the design space for file formats. Each row reveals the file format's internal patterns, which are generated from the same source text. By color-coding each byte within the file, it's possible to see structural differences between each representation.

Table 7.1 The internals of four digital versions of William Shakespeare's *Much Ado About Nothing* produced by Project Gutenberg.

The plain text version of the play contains printable characters only. These are indicated by dark grey for letters and punctuation, and white for whitespace.

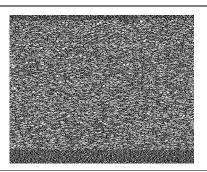

Visually, the image appears to be noisy. It lacks internal structure. That's due to the variation in length of the natural language that the file represents. A file with regular, repeating structures, such as a file format designed to hold arrays of floating-point numbers, tends to look quite different.

The EPUB format is actually a compressed ZIP archive with a bespoke file extension. There are many bytes within the file that fall out of the range of the printable category as indicated by the mid-grey pixels.

MOBI includes four bands of NULL bytes (0x00), represented as black pixels. These bands probably represent the result of an engineering trade-off. In some sense, these empty bytes are wasted space. They're probably added as padding so that the file's sections are easy to parse later on.

The other notable feature of this file is its size. It's larger than the other versions of the play. This might imply that the file is harboring more data than just the text. Candidates include display elements like fonts, or encryption keys that enforce anti-copying restrictions within the file.

Table 7.1 The internals of four digital versions of William Shakespeare's Much Ado About Nothing produced by Project Gutenberg. (continued)

The HTML file contains a high proportion of whitespace characters. These are indicated by white pixels. Markup languages like HTML tend to add whitespace to aid readability.

7.2 Creating your own file formats for data storage

When working with data that needs to be stored over a long time, the proper thing to do is to use a battle-tested database. Despite this, many systems use plain text files for data storage. Configuration files, for example, are commonly designed to be both human-readable and machine-readable. The Rust ecosystem has excellent support for converting data to many on-disk formats.

7.2.1 Writing data to disk with serde and the bincode format

The serde crate *ser*ializes and *de*serializes Rust values to and from many formats. Each format has its own strengths: many are human-readable, while others prefer to be compact so that they can be speedily sent across the network.

Using serde takes surprisingly little ceremony. As an example, let's use statistics about the Nigerian city of Calabar and store those in multiple output formats. To start, let's assume that our code contains a City struct. The serde crate provides the Serialize and Deserialize traits, and most code implements these with this derived annotation:

```
#[derive(Serialize)]
struct City {
   name: String,
   population: usize,
   latitude: f64,
   longitude: f64,
}
Provides the tooling
to enable external
formats to interact
with Rust code
```

Populating that struct with data about Calabar is straightforward. This code snippet shows the implementation:

```
let calabar = City {
   name: String::from("Calabar"),
   population: 470_000,
   latitude: 4.95,
   longitude: 8.33,
};
```

Now to convert that calabar variable to JSON-encoded String. Performing the conversion is one line of code:

```
let as json = to json(&calabar).unwrap();
```

serde understands many more formats than JSON. The code in listing 7.2 (shown later in this section) also provides similar examples for two lesser-known formats: CBOR and bincode. CBOR and bincode are more compact than JSON but at the expense of being machine-readable only.

The following shows the output, formatted for the page, that's produced by listing 7.2. It provides a view of the bytes of the calabar variable in several encodings:

```
$ cargo run
   Compiling ch7-serde-eq v0.1.0 (/rust-in-action/code/ch7/ch7-serde-eq)
   Finished dev [unoptimized + debuginfo] target(s) in 0.27s
     Running `target/debug/ch7-serde-eg`
json:
{"name": "Calabar", "population": 470000, "latitude": 4.95, "longitude": 8.33}

```

To download the project, enter these commands in the console:

```
$ git clone https://github.com/rust-in-action/code rust-in-action
$ cd rust-in-action/ch7-serde-eg
```

To create the project manually, create a directory structure that resembles the following snippet and populate its contents with the code in listings 7.1 and 7.2 from the ch7/ch7-serde-eg directory:

```
ch7-serde-eg
```

```
See listing 7.2.

Cargo.toml

See listing 7.1.
```

Listing 7.1 Declaring dependencies and setting metadata for listing 7.2

```
[package]
name = "ch7-serde-eg"
version = "0.1.0"
authors = ["Tim McNamara <author@rustinaction.com>"]
edition = "2018"

[dependencies]
bincode = "1"
serde = "1"
serde_cbor = "0.8"
serde_derive = "1"
serde_json = "1"
```

Listing 7.2 Serialize a Rust struct to multiple formats

```
1 use bincode::serialize as to bincode;
                                                 These functions are
 2 use serde cbor::to vec as to cbor;
                                                 renamed to shorten
 3 use serde json::to string as to json;
                                                 lines where used.
 4 use serde derive::{Serialize};
 6 #[derive(Serialize)]
                                    Instructs the serde derive
 7 struct City {
                                    crate to write the necessary
       name: String,
                                    code to carry out the
 9
       population: usize,
                                    conversion from an in-memory
10
       latitude: f64,
                                    City to on-disk City
11
       longitude: f64,
12 }
14 fn main() {
15
       let calabar = City {
16
           name: String::from("Calabar"),
           population: 470 000,
17
           latitude: 4.95,
18
19
           longitude: 8.33,
       };
20
21
22
       let as json
                       =
                            to json(&calabar).unwrap();
                                                                Serializes
                                                                into different
23
       let as cbor
                            to cbor(&calabar).unwrap();
                    =
                                                                formats
       let as bincode = to bincode(&calabar).unwrap();
24
       println!("json:\n{}\n", &as json);
26
       println!("cbor:\n{:?}\n", &as cbor);
27
28
       println!("bincode:\n{:?}\n", &as bincode);
29
       println!("json (as UTF-8):\n{}\n",
3.0
          String::from utf8 lossy(as json.as bytes())
31
32
       println!("cbor (as UTF-8):\n{:?}\n",
33
           String::from utf8 lossy(&as cbor)
```

7.3 Implementing a hexdump clone

A handy utility for inspecting a file's contents is hexdump, which takes a stream of bytes, often from a file, and then outputs those bytes in pairs of hexadecimal numbers. Table 7.2 provides an example. As you know from previous chapters, two hexadecimal numbers can represent all digits from 0 to 255, which is the number of bit patterns representable within a single byte. We'll call our clone fview (short for file view).

Table 7.2 fview in operation

```
fview input
    fn main() {
    println!("Hello, world!");
}

fview output
    [0x00000000] 0a 66 6e 20 6d 61 69 6e 28 29 20 7b 0a 20 20 20
    [0x00000010] 20 70 72 69 6e 74 6c 6e 21 28 22 48 65 6c 6c 6f
    [0x00000020] 2c 20 77 6f 72 6c 64 21 22 29 3b 0a 7d
```

Unless you're familiar with hexadecimal notation, the output from fview can be fairly opaque. If you're experienced at looking at similar output, you may notice that there are no bytes above 0x7e (127). There are also few bytes less than 0x21 (33), with the exception of 0x0a (10). 0x0a represents the newline character (\n). These byte patterns are markers for a plain text input source.

Listing 7.4 provides the source code that builds the complete fview. But because a few new features of Rust need to be introduced, we'll take a few steps to get to the full program.

We'll start with listing 7.3, which uses a string literal as input and produces the output in table 7.2. It demonstrates the use of multiline string literals, importing the std::io traits via std::io::prelude. This enables &[u8] types to be read as files via the std::io::Read trait. The source for this listing is in ch7/ch7-fview-str/src/main.rs.

Listing 7.3 A hexdump clone with hard-coded input that mocks file I/O

```
1 use std::io::prelude::*;
2
3 const BYTES_PER_LINE: usize = 16;
4 const INPUT: &'static [u8] = br#"
5 fn main() {
6    println!("Hello, world!");
7 }"#;
8
9 fn main() -> std::io::Result<()> {
```

prelude imports heavily used traits such as Read and Write in I/O operations. It's possible to include the traits manually, but they're so common that the standard library provides this convenience line to help keep your code compact.

Multiline string literals don't need double quotes escaped when built with raw string literals (the r prefix and the # delimiters). The additional b prefix indicates that this should be treated as bytes (&[u8]) not as UTF-8 text (&str).

```
let mut buffer: Vec<u8> = vec!();
10
                                                                       Makes space for the
11
        INPUT.read_to_end(&mut buffer)?;
                                                                       program's input with
12
                                                                       an internal buffer
13
       let mut position in input = 0;
14
        for line in buffer.chunks(BYTES PER LINE) {
                                                                     Reads our input and
15
            print!("[0x{:08x}] ", position in input);
                                                                     inserts it into our
            for byte in line {
16
                                                                     internal buffer
17
                 print!("{:02x} ", byte);
18
                                                                   Writes the current
19
            println!();
                                                                   position with up to 8
20
            position in input += BYTES PER LINE;
                                                                   left-padded zeros
21
22
                                                          Shortcut for printing
23
       Ok(())
                                                          a newline to stdout
24 }
```

Now that we have seen the intended operation of fview, let's extend its capabilities to read real files. The following listing provides a basic hexdump clone that demonstrates how to open a file in Rust and iterate through its contents. You'll find this source in ch7/ch7-fview/src/main.rs.

Listing 7.4 Opening a file in Rust and iterating through its contents

```
1 use std::fs::File;
 2 use std::io::prelude::*;
                                                Changing this constant
 3 use std::env;
                                                changes the program's
                                                output.
 5 const BYTES PER LINE: usize = 16;
 6
 7 fn main() {
     let arg1 = env::args().nth(1);
 8
 9
10
     let fname = arg1.expect("usage: fview FILENAME");
11
     let mut f = File::open(&fname).expect("Unable to open file.");
12
13
     let mut pos = 0;
     let mut buffer = [0; BYTES PER LINE];
14
15
16
       while let Ok(_) = f.read_exact(&mut buffer) {
           print!("[0x{:08x}] ", pos);
17
           for byte in &buffer {
18
19
                match *byte {
                    0x00 => print!(". "),
2.0
21
                    0xff => print!("## "),
                    _ => print!("{:02x} ", byte),
22
23
           }
24
25
           println!("");
26
27
           pos += BYTES PER LINE;
28
29 }
```

Listing 7.4 introduces some new Rust. Let's look at some of those constructs now:

- while let Ok(_) { ... }— With this control-flow structure, the program continues to loop until f.read_exact() returns Err, which occurs when it has run out of bytes to read.
- f.read_exact()—This method from the Read trait transfers data from the source (in our case, f) to the buffer provided as an argument. It stops when that buffer is full.

f.read_exact() provides greater control to you as a programmer for managing memory than the chunks() option used in listing 7.3, but it comes with some quirks. If the buffer is longer than the number of available bytes to read, the file returns an error, and the state of the buffer is undefined. Listing 7.4 also includes some stylistic additions:

- To handle command-line arguments without using third-party libraries, we make use of std::env::args(). It returns an iterator over the arguments provided to the program. Iterators have an nth() method, which extracts the element at the nth position.
- Every iterator's nth() method returns an Option. When n is larger than the length of the iterator, None is returned. To handle these Option values, we use calls to expect().
- The expect() method is considered a friendlier version of unwrap(). expect() takes an error message as an argument, whereas unwrap() simply panics abruptly.

Using std::env::args() directly means that input is not validated. That's a problem in our simple example, but is something to consider for larger programs.

7.4 File operations in Rust

So far in this chapter, we have invested a lot of time considering how data is translated into sequences of bytes. Let's spend some time considering another level of abstraction—the file. Previous chapters have covered basic operations like opening and reading from a file. This section contains some other helpful techniques, which provide more granular control.

7.4.1 Opening a file in Rust and controlling its file mode

Files are an abstraction that's maintained by the operating system (OS). It presents a façade of names and hierarchy above a nest of raw bytes.

Files also provide a layer of security. These have attached permissions that the OS enforces. This (in principle, at least) is what prevents a web server running under its own user account from reading files owned by others.

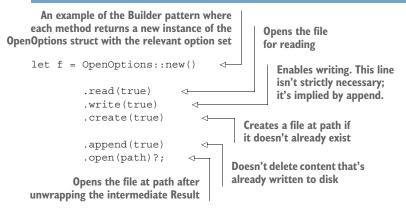

std::fs::File is the primary type for interacting with the filesystem. There are two methods available for creating a file: open() and create(). Use open() when you know the file already exists. Table 7.3 explains more of their differences.

Method	Return value when the file already exists	Effect on the underlying file	Return value when no file exists
File::open	Ok(File)*	Opened as is in read-only mode.	Err
File::create	Ok(File)*	All existing bytes are truncated, and the file is opened at the beginning of the new file.	Ok(File)*

Table 7.3 Creating File values in Rust and the effects on the underlying filesystem

When you require more control, std::fs::OpenOptions is available. It provides the necessary knobs to turn for any intended application. Listing 7.16 provides a good example of a case where an append mode is requested. The application requires a writeable file that is also readable, and if it doesn't already exist, it's created. The following shows an excerpt from listing 7.16 that demonstrates the use of std::fs:OpenOptions to create a writeable file. The file is not truncated when it's opened.

Listing 7.5 Using std::fs:OpenOptions to create a writeable file

7.4.2 Interacting with the filesystem in a type-safe manner with std::fs::Path

Rust provides type-safe variants of str and String in its standard library: std::path:: Path and std::path::PathBuf. You can use these variants to unambiguously work with path separators in a cross-platform way. Path can address files, directories, and related abstractions, such as symbolic links. Path and PathBuf values often start their lives as plain string types, which can be converted with the from() static method:

```
let hello = PathBuf::from("/tmp/hello.txt")
```

From there, interacting with these variants reveals methods that are specific to paths:

^{*} Assuming the user account has sufficient permission.

The full API is straightforward for anyone who has used code to manipulate paths before, so it won't be fleshed out here. Still, it may be worth discussing why it's included within the language because many languages omit this.

NOTE As an implementation detail, std::fs::Path and std::fs::PathBuf are implemented on top of std::ffi::OsStr and std::ffi::OsString, respectively. This means that Path and PathBuf are *not* guaranteed to be UTF-8 compliant.

Why use Path rather than manipulating strings directly? Here are some good reasons for using Path:

- Clear intent—Path provides useful methods like set_extension() that describe
 the intended outcome. This can assist programmers who later read the code.
 Manipulating strings doesn't provide that level of self-documentation.
- Portability—Some operating systems treat filesystem paths as case-insensitive. Others don't. Using one operating system's conventions can result in issues later, when users expect their host system's conventions to be followed. Additionally, path separators are specific to operating systems and, thus, can differ. This means that using raw strings can lead to portability issues. Comparisons require exact matches.
- Easier debugging—If you're attempting to extract /tmp from the path /tmp/hello.txt, doing it manually can introduce subtle bugs that may only appear at runtime. Further, miscounting the correct number of index values after splitting the string on / introduces a bug that can't be caught at compile time.

To illustrate the subtle errors, consider the case of separators. Slashes are common in today's operating systems, but those conventions took some time to become established:

- \ is commonly used on MS Windows.
- / is the convention for UNIX-like operating systems.
- : was the path separator for the classic Mac OS.
- > is used in the Stratus VOS operating system.

Table 7.4 compares the two strings: std::String and std::path::Path.

Table 7.4 Using std::String and std::path::Path to extract a file's parent directory

```
fn main() {
                                           use std::path::PathBuf;
   let hello = String::from("/tmp/
hello.txt");
                                           fn main() {
→ let tmp dir = hello.split("/").nth(0);
                                              let mut hello = PathBuf::from("/tmp/
    println!("{:?}", tmp dir);
                                           hello.txt");
                                              Mistake!
                                               println!("{:?}", hello.display()); <-</pre>
                                  Prints
Splits hello at its backslashes,
                                Some("").
then takes the 0th element of
                                                                    Success! Prints "/tmp".
the resulting Vec<String>
```

Table 7.4 Using std::String and std::path::Path to extract a file's parent directory (continued)

The plain String code lets you use familiar methods, but it can introduce subtle bugs that are difficult to detect at compile time. In this instance, we've used the wrong index number to access the parent directory (/tmp).

Using path::Path doesn't make your code immune to subtle errors, but it can certainly help to minimize their likelihood. Path provides dedicated methods for common operations such as setting a file's extension.

7.5 Implementing a key-value store with a log-structured, append-only storage architecture

It's time to tackle something larger. Let's begin to lift the lid on database technology. Along the way, we'll learn the internal architecture of a family of database systems using a *log-structured*, *append-only* model.

Log-structured, append-only database systems are significant as case studies because these are designed to be extremely resilient while offering optimal read performance. Despite storing data on fickle media like flash storage or a spinning hard disk drive, databases using this model are able to guarantee that data will never be lost and that backed up data files will never be corrupted.

7.5.1 The key-value model

The key-value store implemented in this chapter, actionky, stores and retrieves sequences of bytes ([u8]) of arbitrary length. Each sequence has two parts: the first is a key and the second is a value. Because the &str type is represented as [u8] internally, table 7.5 shows the plain text notation rather than the binary equivalent.

Table 7.5 Illustrating keys and values by matching countries with their capital cities

Кеу	Value
"Cook Islands"	"Avarua"
"Fiji"	"Suva"
"Kiribati"	"South Tarawa"
"Niue"	"Alofi"

The key-value model enables simple queries such as "What is the capital city of Fiji?" But it doesn't support asking broader queries such as "What is the list of capital cities for all Pacific Island states?"

7.5.2 Introducing actionky v1: An in-memory key-value store with a command-line interface

The first version of our key-value store, actionky, exposes us to the API that we'll use throughout the rest of the chapter and also introduces the main library code. The library code will not change as the subsequent two systems are built on top of it. Before we get to that code, though, there are some prerequisites that need to be covered.

Unlike other projects in this book, this one uses the library template to start with (cargo new --lib actionky). It has the following structure:

Using a library crate allows programmers to build reusable abstractions within their projects. For our purposes, we'll use the same lib.rs file for multiple executables. To avoid future ambiguity, we need to describe the executable binaries the actionky project produces.

To do so, provide a bin section within two square bracket pairs ([[bin]]) to the project's Cargo.toml file. See lines 14–16 of the following listing. Two square brackets indicate that the section can be repeated. The source for this listing is in ch7/ch7-actionkv/Cargo.toml.

Listing 7.6 Defining dependencies and other metadata

```
1 [package]
 2 name = "actionkv"
 3 version = "1.0.0"
 4 authors = ["Tim McNamara <author@rustinaction.com>"]
 5 edition = "2018"
                                  Extends Rust types with extra traits to write
                                  those to disk, then reads those back into a
 7 [dependencies]
                            program in a repeatable, easy-to-use way
 8 byteorder = "1.2"
 9 crc = "1.7" <─
                           Provides the checksum functionality that we want to include
10
11 [lib]
                                 This section of Cargo.toml lets you define a
12 name = "libactionkv"
                                 name for the library you're building. Note
13 path = "src/lib.rs"
                               that a crate can only have one library.
15 [[bin]]
                                   A [[bin]] section, of which there can be many, defines an
16 name = "akv mem"
                                    executable file that's built from this crate. The double square
17 path = "src/akv mem.rs"
                                   bracket syntax is required because it unambiguously
                                   describes bin as having one or more elements.
```

Our actionky project will end up with several files. Figure 7.1 illustrates the relationships and how these work together to build the akv_mem executable, referred to within the [[bin]] section of the project's Cargo.toml file.

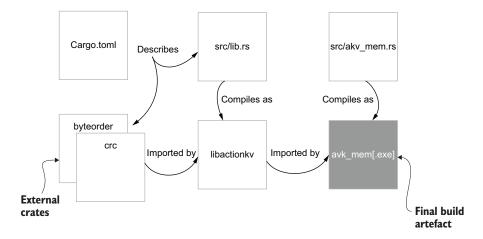

Figure 7.1 An outline of how the different files and their dependencies work together in the actionky project. The project's Cargo.toml coordinates lots of activity that ultimately results in an executable.

7.6 Actionky v1: The front-end code

The public API of actionky is comprised of four operations: get, delete, insert, and update. Table 7.6 describes these operations.

Table 7.6 Operations supported by actionky v1

Command	Description		
get <key></key>	Retrieves the value at key from the store		
insert <key> <value></value></key>	Adds a key-value pair to the store		
delete <key></key>	Removes a key-value pair from the store		
update <key> <value></value></key>	Replaces an old value with a new one		

Naming is difficult

To access stored key-value pairs, should the API provide a get, retrieve, or, perhaps, fetch? Should setting values be insert, store, or set? actionkv attempts to stay neutral by deferring these decisions to the API provided by std::collections:: HashMap.

The following listing, an excerpt from listing 7.8, shows the naming considerations mentioned in the preceding sidebar. For our project, we use Rust's matching facilities to efficiently work with the command-line arguments and to dispatch to the correct internal function.

Listing 7.7 Demonstrating the public API

```
32 match action {
                                                             The action command-line
33
     "get" => match store.get(key).unwrap()
                                                             argument has the type &str.
       None => eprintln!("{:?} not found", key),

50
51 }
```

In full, listing 7.8 presents the code for actionky v1. Notice that the heavy lifting of interacting with the filesystem is delegated to an instance of ActionKV called store. How ActionKV operates is explained in section 7.7. The source for this listing is in ch7/ch7-actionkv1/src/akv_mem.rs.

Listing 7.8 In-memory key-value store command-line application

```
1 use libactionkv::ActionKV;
                                                      Although src/lib.rs exists within our
                                                      project, it's treated the same as any

52 }
```

7.6.1 Tailoring what is compiled with conditional compilation

Rust provides excellent facilities for altering what is compiled depending on the *compiler target architecture*. Generally, this is the target's OS but can be facilities provided by its CPU. Changing what is compiled depending on some compile-time condition is known as *conditional compilation*.

To add conditional compilation to your project, annotate your source code with cfg attributes. cfg works in conjunction with the target parameter provided to ruste during compilation.

Listing 7.8 provides a usage string common as quick documentation for commandline utilities for multiple operating systems. It's replicated in the following listing, which uses conditional compilation to provide two definitions of const USAGE in the code. When the project is built for Windows, the usage string contains a .exe file extension. The resulting binary files include only the data that is relevant for their target.

Listing 7.9 Demonstrating the use of conditional compilation

```
3 #[cfg(target_os = "windows")]
4 const USAGE: &str = "
5 Usage:
6     akv mem.exe FILE get KEY
```

```
7
      akv_mem.exe FILE delete KEY
 8
     akv mem.exe FILE insert KEY VALUE
 9
     akv mem.exe FILE update KEY VALUE
10 ";
11
12 #[cfg(not(target os = "windows"))]
13 const USAGE: &str = "
14 Usage:
15
      akv mem FILE get KEY
     akv mem FILE delete KEY
16
     akv mem FILE insert KEY VALUE
17
18
     akv mem FILE update KEY VALUE
19 ";
```

There is no negation operator for these matches. That is, #[cfg(target_os != "windows")] does not work. Instead, there is a function-like syntax for specifying matches. Use #[cfg(not(...))] for negation. #[cfg(all(...))] and #[cfg(any(...))] are also available to match elements of a list. Lastly, it's possible to tweak cfg attributes when invoking cargo or rustc via the --cfg ATTRIBUTE command-line argument.

The list of conditions that can trigger compilation changes is extensive. Table 7.7 outlines several of these.

Table 7.7 Options available to match against with cfg attributes

Attribute	Valid options	Notes	
target_arch	aarch64, arm, mips, powerpc, powerpc64, x86, x86_64	Not an exclusive list.	
target_os	android, bitrig, dragonfly, freebsd, haiku, ios, linux, macos, netbsd, redox, openbsd, windows	Not an exclusive list.	
target_family	unix, windows		
target_env	"", gnu, msvc, musl	This is often an empty string ("").	
target_endian	big, little		
target_pointer_width	32, 64	The size (in bits) of the target architecture's pointer. Used for isize, usize, * const, and * mut types.	
target_has_atomic	8, 16, 32, 64, ptr	Integer sizes that have support for atomic operations. During atomic operations, the CPU takes responsibility for preventing race conditions with shared data at the expense of performance. The word atomic is used in the sense of indivisible.	

Attribute	Valid options	Notes
target_vendor	apple, pc, unknown	
test		No available options; just uses a simple Boolean check.
debug_assertions		No available options; just uses a simple Boolean check. This attribute is present for non-optimized builds and supports the debug assert! macro.

Table 7.7 Options available to match against with cfg attributes (continued)

7.7 Understanding the core of actionky: The libactionky crate

The command-line application built in section 7.6 dispatches its work to libactionkv::Actionkv. The responsibilities of the Actionkv struct are to manage interactions with the filesystem and to encode and decode data from the on-disk format. Figure 7.2 depicts the relationships.

7.7.1 Initializing the ActionKV struct

Listing 7.10, an excerpt from listing 7.8, shows the initialization process of libactionkv::ActionKV. To create an instance of libactionkv::ActionKV, we need to do the following:

- 1 Point to the file where the data is stored
- 2 Load an in-memory index from the data within the file

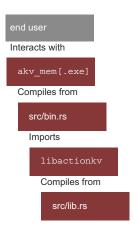

Figure 7.2 Relationship between libactionkv and other components of the actionkv project

Listing 7.10 Initializing libactionkv::ActionKV

```
30 let mut store = ActionKV::open(path)
31 .expect("unable to open file");
32
33 store.load().expect("unable to load data");

Creates an in-memory index by loading the data from path
```

Both steps return Result, which is why the calls to .expect() are also present. Let's now look inside the code of ActionKV::open() and ActionKV::load().open() opens the file from disk, and load() loads the offsets of any pre-existing data into an inmemory index. The code uses two type aliases, ByteStr and ByteString:

```
type ByteStr = [u8];
```

We'll use the ByteStr type alias for data that tends to be used as a string but happens to be in a binary (raw bytes) form. Its text-based peer is the built-in str. Unlike str, ByteStr is not guaranteed to contain valid UTF-8 text.

Both str and [u8] (or its alias ByteStr) are seen in the wild as &str and &[u8] (or &ByteStr). These are both called *slices*.

```
type ByteString = Vec<u8>;
```

The alias ByteString will be the workhorse when we want to use a type that behaves like a String. It's also one that can contain arbitrary binary data. The following listing, an excerpt from listing 7.16, demonstrates the use of ActionKV::open().

Listing 7.11 Using ActionKV::open()

```
12 type ByteString = Vec<u8>;
                                              This code processes lots of Vec<u8> data.
13
                                              Because that's used in the same way as String
14 type ByteStr = [u8];
                                              tends to be used, ByteString is a useful alias.
15
16 #[derive(Debug, Serialize, Deserialize)]
                                                            Instructs the compiler to generate

86
87
                                                 ActionKV::process record() reads a record
88
        let kv = match maybe kv {
                                                         in the file at its current position.
```

```
Ok(kv) => kv,
 89
 90
          Err(err) => {
 91
           match err.kind() {
               io::ErrorKind::UnexpectedEof => {
                                                                Unexpected is relative. The
 93
                                                                application might not have
 94
                                                                expected to encounter the
               _ => return Err(err),
 95
                                                                end of the file, but we expect
 96
                                                                files to be finite, so we'll deal
 97
                                                                with that eventuality.
 98
         };
 99
100
         self.index.insert(kv.key, position);
101
102
103
     Ok(())
104 }
```

What is EOF?

File operations in Rust might return an error of type std::io::ErrorKind::
UnexpectedEof, but what is Eof? The end of file (EOF) is a convention that operating
systems provide to applications. There is no special marker or delimiter at the end
of a file within the file itself.

EOF is a zero byte (0u8). When reading from a file, the OS tells the application how many bytes were successfully read from storage. If no bytes were successfully read from disk, yet no error condition was detected, then the OS and, therefore, the application assume that EOF has been reached.

This works because the OS has the responsibility for interacting with physical devices. When a file is read by an application, the application notifies the OS that it would like to access the disk.

7.7.2 Processing an individual record

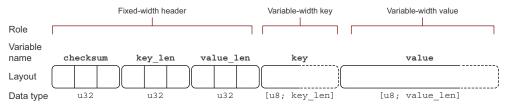

actionky uses a published standard for its on-disk representation. It is an implementation of the Bitcask storage backend that was developed for the original implementation of the Riak database. Bitcask belongs to a family of file formats known in the literature as *Log-Structured Hash Tables*.

What is Riak?

Riak, a NoSQL database, was developed during the height of the NoSQL movement and competed against similar systems such as MongoDB, Apache CouchDB, and Tokyo Tyrant. It distinguished itself with its emphasis on resilience to failure.

Although it was slower than its peers, it guaranteed that it never lost data. That guarantee was enabled in part because of its smart choice of a data format.

Bitcask lays every record in a prescribed manner. Figure 7.3 illustrates a single record in the Bitcask file format.

Specifying an array's type with a variable is not legal Rust but is added here to demonstrate the relationship between the header and the body of each record.

Figure 7.3 A single record in the Bitcask file format. To parse a record, read the header information, then use that information to read the body. Lastly, verify the body's contents with the checksum provided in the header.

Every key-value pair is prefixed by 12 bytes. Those bytes describe its length (key_len + val_len) and its content (checksum).

The process_record() function does the processing for this within ActionKV. It begins by reading 12 bytes that represent three integers: a checksum, the length of the key, and the length of the value. Those values are then used to read the rest of the data from disk and verify what's intended. The following listing, an extract from listing 7.16, shows the code for this process.

Listing 7.12 Focusing on the ActionKV::process record() method

```
f may be any type that implements Read, such as
43 fn process record<R: Read>(
                                             a type that reads files, but can also be &[u8].
44
     f: &mut R
45 ) -> io::Result<KeyValuePair> {
46
        let saved checksum =
                                                     The byteorder crate allows
47
          f.read u32::<LittleEndian>()?;
                                                     on-disk integers to be read
48
        let key len =
                                                     in a deterministic manner
          f.read u32::<LittleEndian>()?;
49
                                                     as discussed in the
50
        let val len =
                                                     following section.
          f.read u32::<LittleEndian>()?;
51
52
        let data len = key len + val len;
53
54
        let mut data = ByteString::with capacity(data len as usize);
55
56
          f.by ref()
57
                                                 f.by ref() is required because take(n)
58
             .take(data len as u64)
                                                 creates a new Read value. Using a
59
             .read to end(&mut data)?;
                                                 reference within this short-lived
                                                 block sidesteps ownership issues.
```

```
61
       debug assert eq!(data.len(), data len as usize);

```

A checksum (a number) verifies that the bytes read from disk are the same as what was intended. This process is discussed in section 7.7.4.

7.7.3 Writing multi-byte binary data to disk in a guaranteed byte order

One challenge that our code faces is that it needs to be able to store multi-byte data to disk in a deterministic way. This sounds easy, but computing platforms differ as to how numbers are read. Some read the 4 bytes of an i32 from left to right; others read from right to left. That could potentially be a problem if the program is designed to be written by one computer and loaded by another.

The Rust ecosystem provides some support here. The byteorder crate can extend types that implement the standard library's std::io::Read and std::io::Write traits. std::io::Read and std::io::Write are commonly associated with std::io::File but are also implemented by other types such as [u8] and TcpStream. The extensions can guarantee how multi-byte sequences are interpreted, either as little endian or big endian.

To follow what's going on with our key-value store, it will help to have an understanding of how byteorder works. Listing 7.14 is a toy application that demonstrates the core functionality. Lines 11–23 show how to write to a file and lines 28–35 show how to read from one. The two key lines are

```
use byteorder::{LittleEndian};
use byteorder::{ReadBytesExt, WriteBytesExt};
```

byteorder::LittleEndian and its peers BigEndian and NativeEndian (not used in listing 7.14) are types that declare how multi-byte data is written to and read from disk. byteorder::ReadBytesExt and byteorder::WriteBytesExt are traits. In some sense, these are invisible within the code.

These extend methods to primitive types such as £32 and £16 without further ceremony. Bringing those into scope with a use statement immediately adds powers to the types that are implemented within the source of byteorder (in practice, that means primitive types). Rust, as a statically-typed language, makes this transformation at

compile time. From the running program's point of view, integers always have the ability to write themselves to disk in a predefined order.

When executed, listing 7.14 produces a visualization of the byte patterns that are created by writing 1 u32, 2 i8, and 3.0 f32 in little-endian order. Here's the output:

```
[1, 0, 0, 0]
[1, 0, 0, 0, 2]
[1, 0, 0, 0, 2, 0, 0, 0, 0, 0, 0, 8, 64]
```

The following listing shows the metadata for the project in listing 7.14. You'll find the source code for the following listing in ch7/ch7-write123/Cargo.toml. The source code for listing 7.14 is in ch7/ch7-write123/src/main.rs.

Listing 7.13 Metadata for listing 7.14

```

38 assert_eq!(two, two_);
39
   assert eq!(three, three);
40 }
```

7.7.4 Validating I/O errors with checksums

actionky v1 has no method of validating that what it has read from disk is what was written to disk. What if something is interrupted during the original write? We may not be able to recover the original data if this is the case, but if we could recognize the issue, then we would be in a position to alert the user.

A well-worn path to overcome this problem is to use a technique called a *checksum*. Here's how it works:

Saving to disk—Before data is written to disk, a checking function (there are
many options as to which function) is applied to those bytes. The result of the
checking function (the checksum) is written alongside the original data.

No checksum is calculated for the bytes of the checksum. If something breaks while writing the checksum's own bytes to disk, this will be noticed later as an error.

• Reading from disk—Read the data and the saved checksum, applying the checking function to the data. Then compare the results of the two checking functions. If the two results do not match, an error has occurred, and the data should be considered corrupted.

Which checking function should you use? Like many things in computer science, it depends. An ideal checksum function would

- Return the same result for the same input
- Always return a different result for different inputs
- Be fast
- Be easy to implement

Table 7.8 compares the different checksum approaches. To summarize

- The parity bit is easy and fast, but it is somewhat prone to error.
- CRC32 (cyclic redundancy check returning 32 bits) is much more complex, but its results are more trustworthy.
- Cryptographic hash functions are more complex still. Although being significantly slower, they provide high levels of assurance.

Table 7.8 A simplistic evaluation of different checksum functions

Checksum technique	Size of result	Simplicity	Speed	Reliability
Parity bit	1 bit	****	****	***
CRC32	32 bits	****	****	***
Cryptographic hash function	128-512 bits (or more)	****	***	****

Functions that you might see in the wild depend on your application domain. More traditional areas might see the use of simpler systems, such as a parity bit or CRC32.

IMPLEMENTING PARITY BIT CHECKING

This section describes one of the simpler checksum schemes: *parity checking*. Parity checks count the number of 1s within a bitstream. These store a bit that indicates whether the count was even or odd.

Parity bits are traditionally used for error detection within noisy communication systems, such as transmitting data over analog systems such as radio waves. For example, the ASCII encoding of text has a particular property that makes it quite convenient for this scheme. Its 128 characters only require 7 bits of storage ($128 = 2^7$). That leaves 1 spare bit in every byte.

Systems can also include parity bits in larger streams of bytes. Listing 7.15 presents an (overly chatty) implementation. The parity_bit() function in lines 1–10 takes an arbitrary stream of bytes and returns a u8, indicating whether the count of the input's bits was even or odd. When executed, listing 7.15 produces the following output:

```
input: [97, 98, 99]
                                     input: [97, 98, 99] represents
97 (0b01100001) has 3 one bits
                                    b"abc" as seen by the internals
98 (0b01100010) has 3 one bits
                                    of the Rust compiler.
99 (0b01100011) has 4 one bits
output: 00000001
input: [97, 98, 99, 100]
                                    input: [97, 98, 99,
97 (0b01100001) has 3 one bits
                                    100] represents
98 (0b01100010) has 3 one bits
                                    b"abcd".
99 (0b01100011) has 4 one bits
100 (0b01100100) has 3 one bits
result: 00000000
```

NOTE The code for the following listing is in ch7/ch7-paritybit/src/main.rs.

Listing 7.15 Implementing parity bit checking

```
All of Rust's integer types come equipped with
                                                           Takes a byte slice as the bytes
count ones() and count zeros() methods.
                                                            argument and returns a single
                                                           byte as output. This function could
     1 fn parity bit(bytes: &[u8]) -> u8 {
                                                            have easily returned a bool value,
          let mut n ones: u32 = 0;
                                                           but returning u8 allows the result
     3
                                                           to bit shift into some future
         for byte in bytes {
                                                           desired position.
     5
            let ones = byte.count ones();
     6
            n ones += ones;
     7
            println!("{} (0b{:08b}) has {} one bits", byte, byte, ones);
     8
     9
          (n_{ones % 2 == 0}) as u8
                                                  There are plenty of methods to optimize this
    10 }
                                                  function. One fairly simple approach is to hard
    11
                                                  code a const [u8; 256] array of 0s and 1s,
    12 fn main() {
                                                  corresponding to the intended result, then
        let abc = b"abc";
                                                 index that array with each byte.
         println!("input: {:?}", abc);
    15
         println!("output: {:08x}", parity_bit(abc));
    16
         println!();
    17
         let abcd = b"abcd";
          println!("input: {:?}", abcd);
    19
        println!("result: {:08x}", parity_bit(abcd))
    20 }
```

7.7.5 Inserting a new key-value pair into an existing database

As discussed in section 7.6, there are four operations that our code needs to support: insert, get, update, and delete. Because we're using an append-only design, this means that the last two operations can be implemented as variants of insert.

You may have noticed that during <code>load()</code>, the inner loop continues until the end of the file. This allows more recent updates to overwrite stale data, including deletions. Inserting a new record is almost the inverse of <code>process_record()</code>, described in section 7.7.2. For example

```
164 pub fn insert(
165 &mut self,
166 key: &ByteStr,
167 value: &ByteStr
168 ) -> io::Result<()> {
169
      let position = self.insert but ignore index(key, value)?;
170
171
      self.index.insert(key.to vec(), position);
                                                                key.to vec() converts the
      Ok(())
172
                                                                &ByteStr to a ByteString.
173 }
174
                                                            The std::io::BufWriter type batches
175 pub fn insert but ignore index(
                                                            multiple short write() calls into
176 &mut self,
                                                            fewer actual disk operations,
177
    key: &ByteStr,
                                                            resulting in a single one. This
178 value: &ByteStr
                                                            increases throughput while keeping
179 ) -> io::Result<u64> {
                                                            the application code neater.
180
      let mut f = BufWriter::new(&mut self.f);
181
```

```
let key len = key.len();
182
183
      let val len = value.len();
184
     let mut tmp = ByteString::with capacity(key len + val len);
185
186
     for byte in key {
187
        tmp.push(*byte);
                                Iterating through one
188
                                 collection to populate another
189
                                 is slightly awkward, but gets
190
      for byte in value {
                                 the job done.
191
      tmp.push(*byte);
192
193
194
     let checksum = crc32::checksum ieee(&tmp);
195
196
     let next byte = SeekFrom::End(0);
197 let current position = f.seek(SeekFrom::Current(0))?;
198
     f.seek(next byte)?;
199 f.write u32::<LittleEndian>(checksum)?;
200 f.write u32::<LittleEndian>(key len as u32)?;
201 f.write_u32::<LittleEndian>(val_len as u32)?;
202
    f.write all(&mut tmp)?;
203
204
     Ok(current position)
205 }
```

7.7.6 The full code listing for actionky

libactionkv performs the heavy lifting in our key-value stores. You have already explored much of the actionkv project throughout section 7.7. The following listing, which you'll find in the file ch7/ch7-actionkv1/src/lib.rs, presents the project code in full.

Listing 7.16 The actionky project (full code)

```
1 use std::collections::HashMap;
 2 use std::fs::{File, OpenOptions};
 3 use std::io;
 4 use std::io::prelude::*;
 5 use std::io::{BufReader, BufWriter, SeekFrom};
 6 use std::path::Path;
 8 use byteorder::{LittleEndian, ReadBytesExt, WriteBytesExt};
9 use crc::crc32;
10 use serde derive::{Deserialize, Serialize};
12 type ByteString = Vec<u8>;
13 type ByteStr = [u8];
14
15 #[derive(Debug, Serialize, Deserialize)]
16 pub struct KeyValuePair {
17 pub key: ByteString,
    pub value: ByteString,
18
19 }
20
```

```
21 #[derive(Debug)]
22 pub struct ActionKV {
23
     f: File,
     pub index: HashMap<ByteString, u64>,
25 }
26
27 impl ActionKV {
28
    pub fn open(
29
       path: &Path
30
     ) -> io::Result<Self> {
31
      let f = OpenOptions::new()
         .read(true)
32
33
         .write(true)
34
         .create(true)
35
         .append(true)
36
         .open(path)?;
37
       let index = HashMap::new();
38
       Ok(ActionKV { f, index })
                                            process record() assumes
39
     }
                                            that f is already at the right
40
                                            place in the file.
41
     fn process record<R: Read>(
42
       f: &mut R
43
     ) -> io::Result<KeyValuePair> {
44
       let saved checksum =
         f.read u32::<LittleEndian>()?;
45

If you've made it this far, you should congratulate yourself. You've implemented a key-value store that will happily store and retrieve whatever you have to throw at it.

7.7.7 Working with keys and values with HashMap and BTreeMap

Working with key-value pairs happens in almost every programming language. For the tremendous benefit of learners everywhere, this task and the data structures that support it have many names:

- You might encounter someone with a computer science background who prefers to use the term hash table.
- Perl and Ruby call these hashes.
- Lua does the opposite and uses the term *table*.

- Many communities name the structure after a metaphor such as a dictionary or a map.
- Other communities prefer naming based on the role that the structure plays.
- PHP describes these as associative arrays.
- JavaScript's objects tend to be implemented as a key-value pair collection and so the generic term *object* suffices.
- Static languages tend to name these according to how they are implemented.
- C++ and Java distinguish between a *hash map* and a *tree map*.

Rust uses the terms HashMap and BTreeMap to define two implementations of the same abstract data type. Rust is closest to C++ and Java in this regard. In this book, the terms collection of key-value pairs and associative array refer to the abstract data type. Hash table refers to associative arrays implemented with a hash table, and a HashMap refers to Rust's implementation of hash tables.

What is a hash? What is hashing?

If you've ever been confused by the term *hash*, it may help to understand that this relates to an implementation decision made to enable non-integer keys to map to values. Hopefully, the following definitions will clarify the term:

- A HashMap is implemented with a hash function. Computer scientists will understand that this implies a certain behavior pattern in common cases. A hash map has a constant time lookup in general, formally denoted as O(1) in big O notation. (Although a hash map's performance can suffer when its underlying hash function encounters some pathological cases as we'll see shortly.)
- A hash function maps between values of variable-length to fixed-length. In practice, the return value of a hash function is an integer. That fixed-width value can then be used to build an efficient lookup table. This internal lookup table is known as a hash table.

The following example shows a basic hash function for &str that simply interprets the first character of a string as an unsigned integer. It, therefore, uses the first character of the string as an hash value:

| The .chars() iterator converts

```
the string into a series of char
fn basic hash(key: &str) -> u32 {
                                             values, each 4 bytes long.
    let first = key.chars()
                                                       Returns an Option that's
                                                      either Some(char) or None
                                                     for empty strings
    u32::from(first)
                                                     If an empty string, provides
}
                                                     NULL as the default.
                     Interprets the
                                                    unwrap or() behaves as
               memory of first as an
                                                     unwrap() but provides a
                u32, even though its
                                                    value rather than panicking
                        type is char
                                                    when it encounters None.
```

basic_hash can take any string as input—an infinite set of possible inputs—and return a fixed-width result for all of those in a deterministic manner. That's great! But, although basic hash is fast, it has some significant faults.

If multiple inputs start with the same character (for example, *Tonga* and *Tuvalu*), these result in the same output. This happens in every instance when an infinite input space is mapped into a finite space, but it's particularly bad here. Natural language text is not uniformly distributed.

Hash tables, including Rust's HashMap, deal with this phenomenon, which is called a hash collision. These provide a backup location for keys with the same hash value. That secondary storage is typically a Vec<T> that we'll call the collision store. When collisions occur, the collision store is scanned from front to back when it is accessed. That linear scan takes longer and longer to run as the store's size increases. Attackers can make use of this characteristic to overload the computer that is performing the hash function.

In general terms, faster hash functions do less work to avoid being attacked. These will also perform best when their inputs are within a defined range.

Fully understanding the internals of how hash tables are implemented is too much detail for this sidebar. But it's a fascinating topic for programmers who want to extract optimum performance and memory usage from their programs.

7.7.8 Creating a HashMap and populating it with values

The next listing provides a collection of key-value pairs encoded as JSON. It uses some Polynesian island nations and their capital cities to show the use of an associative array.

Listing 7.17 Demonstrating the use of an associative array in JSON notation

```
{
  "Cook Islands": "Avarua",
  "Fiji": "Suva",
  "Kiribati": "South Tarawa",
  "Niue": "Alofi",
  "Tonga": "Nuku'alofa",
  "Tuvalu": "Funafuti"
}
```

Rust does not provide a literal syntax for HashMap within the standard library. To insert items and get them out again, follow the example provided in listing 7.18, whose source is available in ch7/ch7-pacific-basic/src/main.rs. When executed, listing 7.18 produces the following line in the console:

Capital of Tonga is: Nuku'alofa

Listing 7.18 An example of the basic operations of HashMap

```
1 use std::collections::HashMap;
2
3 fn main() {
```

```
let mut capitals = HashMap::new();
 4
                                                          Type declarations of keys and
 5
                                                          values are not required here
 6
     capitals.insert("Cook Islands", "Avarua");
                                                          as these are inferred by the
     capitals.insert("Fiji", "Suva");
 7
                                                          Rust compiler.
     capitals.insert("Kiribati", "South Tarawa");
 8
     capitals.insert("Niue", "Alofi");
 9
                                                            HashMap implements Index,
     capitals.insert("Tonga", "Nuku'alofa");
10
                                                            which allows for values to
     capitals.insert("Tuvalu", "Funafuti");
11
                                                            be retrieved via the square
12
                                                           bracket indexing style.
     let tongan capital = capitals["Tonga"];
13
14
     println!("Capital of Tonga is: {}", tongan capital);
15
16 }
```

Writing everything out as method calls can feel needlessly verbose at times. With some support from the wider Rust ecosystem, it's possible to inject JSON string literals into Rust code. It's best that the conversion is done at compile time, meaning no loss of runtime performance. The output of listing 7.19 is also a single line:

```
Capital of Tonga is: "Nuku'alofa"

Uses double quotes because the json! macro returns a wrapper around
String, its default representation
```

The next listing uses a serde-json crate to include JSON literals within your Rust source code. Its source code is in the ch7/ch7-pacific-json/src/main.rs file.

Listing 7.19 Including JSON literals with serde-json

```
Incorporates the serde json crate
 1 #[macro use]
                                         and makes use of its macros, bringing
 2 extern crate serde json;
                                         the json! macro into scope
 4 fn main() {
     let capitals = json!({
                                             json! takes a JSON literal and some
 6
        "Cook Islands": "Avarua",
                                             Rust expressions to implement String
 7
        "Fiji": "Suva",
                                             values. It converts these into a Rust
 8
        "Kiribati": "South Tarawa",
                                             value of type serde_json::Value, an
 9
        "Niue": "Alofi",
                                             enum that can represent every type
        "Tonga": "Nuku'alofa",
10
                                            within the JSON specification.
       "Tuvalu": "Funafuti"
11
12
     });
13
     println!("Capital of Tonga is: {}", capitals["Tonga"])
14
15 }
```

7.7.9 Retrieving values from HashMap and BTreeMap

The main advantage that a key-value store provides is the ability to access its values. There are two ways to achieve this. To demonstrate, let's assume that we have initialized capitals from listing 7.19. The approach (already demonstrated) is to access values via square brackets:

```
capitals["Tonga"] <------ Returns "Nuku'alofa"
```

This approach returns a read-only reference to the value, which is deceptive when dealing with examples containing string literals because their status as references is somewhat disguised. In the syntax used by Rust's documentation, this is described as &V, where & denotes a read-only reference and V is the type of the value. If the key is not present, the program will panic.

NOTE Index notation is supported by all types that implement the Index trait. Accessing capitals ["Tonga"] is syntactic sugar for capitals.index("Tonga").

It's also possible to use the .get() method on HashMap. This returns an Option<&V>, providing the opportunity to recover from cases where values are missing. For example

```
capitals.get("Tonga") <----- Returns Some("Nuku'alofa")
```

Other important operations supported by HashMap include

- Deleting key-value pairs with the .remove() method
- Iterating over keys, values, and key-value pairs with the .keys(), .values(), and .iter() methods, respectively, as well as their read-write variants, .keys_mut(), .values mut(), and .iter mut()

There is no method for iterating through a subset of the data. For that, we need to use BTreeMap.

7.7.10 How to decide between HashMap and BTreeMap

If you're wondering about which backing data structure to choose, here is a simple guideline: use HashMap unless you have a good reason to use BTreeMap. BTreeMap is faster when there is a natural ordering between the keys, and your application makes use of that arrangement. Table 7.9 highlights the differences.

Let's demonstrate these two use cases with a small example from Europe. The Dutch East India Company, known as VOC after the initials of its Dutch name, Vereenigde Oostindische Compagnie, was an extremely powerful economic and political force at its peak. For two centuries, VOC was a dominant trader between Asia and Europe. It had its own navy and currency, and established its own colonies (called trading posts). It was also the first company to issue bonds. In the beginning, investors from six business chambers (kamers) provided capital for the business.

Let's use these investments as key-value pairs. When listing 7.20 is compiled, it produces an executable that generates the following output:

```
$ cargo run -q
```

Rotterdam invested 173000
Hoorn invested 266868
Delft invested 469400
Enkhuizen invested 540000
Middelburg invested 1300405
Amsterdam invested 3697915
smaller chambers: Rotterdam Hoorn Delft

Listing 7.20 Demonstrating range queries and ordered iteration of BTreeMap

```
1 use std::collections::BTreeMap;
              3 fn main() {
                 let mut voc = BTreeMap::new();
              6
                 voc.insert(3_697_915, "Amsterdam");
              7
                 voc.insert(1 300 405, "Middelburg");
                 voc.insert( 540 000, "Enkhuizen");
                 voc.insert( 469 400, "Delft");
              9
                 voc.insert( 266 868, "Hoorn");
             10
                 voc.insert( 173 000, "Rotterdam");
             11
            12
                                                                               BTreeMap lets you
             13
                  for (quilders, kamer) in &voc {
            14
                  println!("{} invested {}", kamer, guilders);
                                                                               select a portion of
                                                                               the keys that are
             15
Prints in
                                                                               iterated through
            16
 sorted
                                                                               with the range
                  print!("smaller chambers: ");
             17
  order
                                                                               syntax.
             18
                 for (_guilders, kamer) in voc.range(0..500_000) {
            19
                    print!("{} ", kamer);
            20
             21
                  println!("");
            22 }
```

Table 7.9 Deciding on which implementation to use to map keys to values

```
std::collections::HashMap with a
default hash function (known as SipHash
in the literature)

std::collections::BTreeMap

Cryptographically secure and resistant to denial
of service attacks but slower than alternative hash
functions

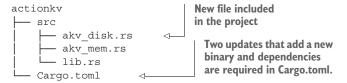

Useful for keys with an inherent ordering, where
cache coherence can provide a boost in speed
```

7.7.11 Adding a database index to actionky v2.0

Databases and filesystems are much larger pieces of software than single files. There is a large design space involved with storage and retrieval systems, which is why new ones are always being developed. Common to all of those systems, however, is a component that is the real smarts behind the database.

Built in section 7.5.2, actionky v1 contains a major issue that prevents it from having a decent startup time. Every time it's run, it needs to rebuild its index of where keys are stored. Let's add the ability for actionky to store its own data that indexes within the same file that's used to store its application data. It will be easier than it sounds. No changes to libactionky are necessary. And the front-end code only requires minor additions. The project folder now has a new structure with an extra file (shown in the following listing).

Listing 7.21 The updated project structure for actionky v2.0

The project's Cargo.toml adds some new dependencies along with a second [[bin]] entry, as the last three lines of the following listing show. The source for this listing is in ch7/ch7-actionkv2/Cargo.toml.

Listing 7.22 Updating the Cargo.toml file for actionky v2.0

```
[package]
name = "actionkv"
version = "2.0.0"
authors = ["Tim McNamara <author@rustinaction.com>"]
edition = "2018"
[dependencies]
bincode = "1"
                           New dependencies to
byteorder = "1"
                           assist with writing
crc = "1"
                           the index to disk
serde = "1"
serde derive = "1"
[lib]
name = "libactionky"
path = "src/lib.rs"
[[bin]]
name = "akv mem"
path = "src/akv mem.rs"
[[bin]]
name = "akv disk"
                                New executable
path = "src/akv disk.rs"
                               definition
```

When a key is accessed with the get operation, to find its location on disk, we first need to load the index from disk and convert it to its in-memory form. The following listing is an excerpt from listing 7.24. The on-disk implementation of actionky includes a hidden INDEX KEY value that allows it to quickly access other records in the file.

Listing 7.23 Highlighting the main change from listing 7.8

```
53
54
       let index decoded = bincode::deserialize(&index as bytes);
55
       let index: HashMap<ByteString, u64> = index decoded.unwrap();
56
57
58
      match index.get(key) {
                                                            Retrieving a value
        None => eprintln!("{:?} not found", key),
59
                                                            now involves fetching
         Some(&i) => {
60
                                                            the index first, then
61
            let kv = a.get at(i).unwrap();
                                                            identifying the correct
            println!("{:?}", kv.value)
                                                            location on disk.
63
       }
64
     }
65
```

The following listing shows a key-value store that persists its index data between runs. The source for this listing is in ch7/ch7-actionkv2/src/akv_disk.rs.

Listing 7.24 Persisting index data between runs

```
1 use libactionkv::ActionKV;
 2 use std::collections::HashMap;
 4 #[cfg(target_os = "windows")]
 5 const USAGE: &str = "
 6 Usage:
 7
       akv disk.exe FILE get KEY
 8
       akv disk.exe FILE delete KEY
 9
       akv disk.exe FILE insert KEY VALUE
       akv disk.exe FILE update KEY VALUE
10
11 ";
12
13 #[cfq(not(target os = "windows"))]
14 const USAGE: &str = "
15 Usage:
16
       akv disk FILE get KEY
17
       akv disk FILE delete KEY
18
      akv_disk FILE insert KEY VALUE
19
       akv disk FILE update KEY VALUE
20 ";
22 type ByteStr = [u8];
23 type ByteString = Vec<u8>;
24
25 fn store index on disk(a: &mut ActionKV, index key: &ByteStr) {
     a.index.remove(index key);
27
    let index as bytes = bincode::serialize(&a.index).unwrap();
    a.index = std::collections::HashMap::new();
     a.insert(index_key, &index_as_bytes).unwrap();
30 }
31
32 fn main() {
    const INDEX KEY: &ByteStr = b"+index";
34
35
     let args: Vec<String> = std::env::args().collect();
```

Summary 249

```
let fname = args.get(1).expect(&USAGE);
36
37
     let action = args.get(2).expect(&USAGE).as ref();
38
     let key = args.get(3).expect(&USAGE).as ref();
39
     let maybe value = args.get(4);
40
41
     let path = std::path::Path::new(&fname);
     let mut a = ActionKV::open(path).expect("unable to open file");
42
43
44
     a.load().expect("unable to load data");
45
46
     match action {
47
       "get" => {
48
         let index as bytes = a.get(&INDEX KEY)
49
                                         .unwrap()
50
                                         .unwrap();
51
52
         let index decoded = bincode::deserialize(&index as bytes);
53
         let index: HashMap<ByteString, u64> = index decoded.unwrap();
54
55
56
         match index.get(key) {
57
           None => eprintln!("{:?} not found", key),
58
           Some(&i) => {
59
             let kv = a.get at(i).unwrap();
             println!("{:?}", kv.value)
60
                                                    To print values, we need to
61
                                                    use Debug as an [u8] value
62
         }
                                                    contains arbitrary bytes.
       }
63
64
65
       "delete" => a.delete(key).unwrap(),
66
67
       "insert" => {
68
         let value = maybe value.expect(&USAGE).as ref();
69
         a.insert(key, value).unwrap();
70
        store_index_on_disk(&mut a, INDEX_KEY);
71
                                                               The index must
72
                                                               also be updated
73
       "update" => {
                                                               whenever the
74
        let value = maybe value.expect(&USAGE).as ref();
                                                               data changes.
         a.update(key, value).unwrap();
75
76
         store index on disk(&mut a, INDEX KEY);
77
78
       _ => eprintln!("{}", &USAGE),
79
80 }
```

Summary

- Converting between in-memory data structures and raw byte streams to be stored in files or sent over the network is known as *serialization* and *deserializa*tion. In Rust, serde is the most popular choice for these two tasks.
- Interacting with the filesystem almost always implies handling std::io::ResultResult is used for errors that are not part of normal control flow.

- Filesystem paths have their own types: std::path::Path and std::path::PathBuf. While it adds to the learning burden, implementing these allows you to avoid common mistakes that can occur by treating paths directly as strings.
- To mitigate the risk of data corruption during transit and storage, use checksums and parity bits.
- Using a library crate makes it easier to manage complex software projects. Libraries can be shared between projects, and you can make these more modular.
- There are two primary data structures for handling key-value pairs within the Rust standard library: HashMap and BTreeMap. Use HashMap unless you know that you want to make use of the features offered by BTreeMap.
- The cfq attribute and cfq! macro allow you to compile platform-specific code.
- To print to standard error (stderr), use the eprintln! macro. Its API is identical to the println! macro that is used to print to standard output (stdout).
- The Option type is used to indicate when values may be missing, such as asking for an item from an empty list.

Networking

This chapter covers

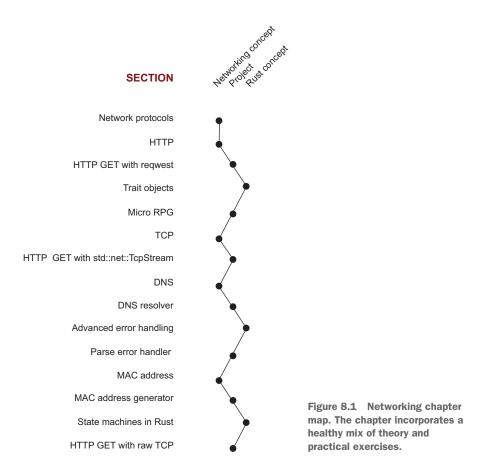

- Implementing a networking stack
- Handling multiple error types within local scope
- When to use trait objects
- Implementing state machines in Rust

This chapter describes how to make HTTP requests multiple times, stripping away a layer of abstraction each time. We start by using a user-friendly library, then boil that away until we're left with manipulating raw TCP packets. When we're finished, you'll be able to distinguish an IP address from a MAC address. And you'll learn why we went straight from IPv4 to IPv6.

You'll also learn lots of Rust in this chapter, most of it related to advanced error handling techniques that become essential for incorporating upstream crates. Several pages are devoted to error handling. This includes a thorough introduction to trait objects.

Networking is a difficult subject to cover in a single chapter. Each layer is a fractal of complexity. Networking experts will hopefully overlook my lack of depth in treating such a diverse topic.

Figure 8.1 provides an overview of the topics that the chapter covers. Some of the projects that we cover include implementing DNS resolution and generating standards-compliant MAC addresses, including multiple examples of generating HTTP requests. A bit of a role-playing game is added for light relief.

8.1 All of networking in seven paragraphs

Rather than trying to learn the whole networking stack, let's focus on something that's of practical use. Most readers of this book will have encountered web programming. Most web programming involves interacting with some sort of framework. Let's look there.

HTTP is the protocol that web frameworks understand. Learning more about HTTP enables us to extract the most performance out of our web frameworks. It can also help us to more easily diagnose any problems that occur. Figure 8.2 shows networking protocols for content delivery over the internet.

Networking is comprised of layers. If you're new to the field, don't be intimidated by a flood of acronyms. The most important thing to remember is that lower levels are

How computers talk to each other

TCPIIP model .OSI model LOCAL DECOMPRESSION, DECODING AND PRESENTATION **ABOUT** A view of the networking stack. Each layer relies upon the layers below it. APPLICATION Occassionally layers bleed together. For example, HTML files can include directives that 5 7 HTTP overwrite those provided by DATABASE HTTP. TLS For a message to be received, TRANSPORT each layer must be traversed DNS from bottom to top. To send messages, the steps are 4 TCP reversed. ARP **HOW TO READ** 3 IPv4 Vertical positioning typically indicates that two levels interact MAC ADDRESS at that location. 2 Exceptions include encryption 1 provided by TLS. Network addressing provided by either IPv4 or IPv6, and virtual CONTACT INFO layers are largely ignorant of physical links. (Shadows from physics do appear on upper layers in the form of latency and reliability.) Gaps indicate that a higher level can pass directly through to the lower level. A domain name or TLS security is not necessary for HTTP to function, for example. **LEGEND** Protocol discussed in this chapter Protocol in use at this level Represents hundreds of other protocols that exist at this level This protocol is available, but may not be deployed.

Figure 8.2 Several layers of networking protocols involved with delivering content over the internet. The figure compares some common models, including the seven-layer OSI model and the four-layer TCP/IP model.

unaware of what's happening above them, and higher levels are agnostic to what's happening below them. Lower levels receive a stream of bytes and pass it on. Higher levels don't care how messages are sent; they just want them sent.

Let's consider one example: HTTP. HTTP is known as an *application-level protocol*. Its job is to transport content like HTML, CSS, JavaScript, WebAssembly modules, images, video, and other formats. These formats often include other embedded formats via compression and encoding standards. HTTP itself often redundantly includes information provided by one of the layers below it, TCP. Between HTTP and TCP sits TLS. TLS (Transport Layer Security), which has replaced SSL (Secure Sockets Layer), adds the S to HTTPS.

TLS provides encrypted messaging over an unencrypted connection. TLS is implemented on top of TCP. TCP sits upon many other protocols. These go all the way down to specifying how voltages should be interpreted as 0s and 1s. And yet, as complicated as this story is so far, it gets worse. These layers, as you have probably seen in your dealings with those as a computer user, bleed together like watercolor paint.

HTML includes a mechanism to supplement or overwrite directives omitted or specified within HTTP: the <meta> tag's http-equiv attribute. HTTP can make adjustments downwards to TCP. The "Connection: keep-alive" HTTP header instructs TCP to maintain its connection after this HTTP message has been received. These sorts of interactions occur all through the stack. Figure 8.2 provides one view of the networking stack. It is more complicated than most attempts. And even that complicated picture is highly simplified.

Despite all of that, we're going to try to implement as many layers as possible within a single chapter. By the end of it, you will be sending HTTP requests with a virtual networking device and a minimal TCP implementation that you created yourself, using a DNS resolver that you also created yourself.

8.2 Generating an HTTP GET request with request

Our first implementation will be with a high-level library that is focused on HTTP. We'll use the request library because its focus is primarily on making it easy for Rust programmers to create an HTTP request.

Although it's the shortest, the request implementation is the most feature-complete. As well as being able to correctly interpret HTTP headers, it also handles cases like content redirects. Most importantly, it understands how to handle TLS properly.

In addition to expanded networking capabilities, request also validates the content's encoding and ensures that it is sent to your application as a valid String. None of our lower-level implementations do any of that. The following shows the project structure for listing 8.2:

The following listing shows the metadata for listing 8.2. The source code for this listing is in ch8/ch8-simple/Cargo.toml.

Listing 8.1 Crate metadata for listing 8.2

```
[package]
name = "ch8-simple"
version = "0.1.0"
authors = ["Tim McNamara <author@rustinaction.com>"]
edition = "2018"

[dependencies]
reqwest = "0.9"
```

The following listing illustrates how to make an HTTP request with the request library. You'll find the source in ch8/ch8-simple/src/main.rs.

Listing 8.2 Making an HTTP request with reqwest

```
1 use std::error::Error;
 2
 3 use reqwest;
 5 fn main() -> Result<(), Box<dyn Error>> {
                                                       Box < dyn Error >
    let url = "http://www.rustinaction.com/";
                                                       represents a trait
 7
    let mut response = reqwest::get(url)?;
                                                       object, which we'll
 8
                                                      cover in section 8.3.
 9 let content = response.text()?;
10 print!("{}", content);
11
12
   Ok(())
13 }
```

If you've ever done any web programming, listing 8.2 should be straightforward. reqwest::get() issues an HTTP GET request to the URL represented by url. The response variable holds a struct representing the server's response. The response .text() method returns a Result that provides access to the HTTP body after validating that the contents are a legal String.

One question, though: What on earth is the error side of the Result return type Box<dyn std::error::Error>? This is an example of a trait object that enables Rust to support polymorphism at runtime. *Trait objects* are proxies for concrete types. The syntax Box<dyn std::error::Error> means a Box (a pointer) to any type that implements std::error:Error's.

Using a library that knows about HTTP allows our programs to omit many details. For example

• *Knowing when to close the connection*. HTTP has rules for telling each of the parties when the connection ends. This isn't available to us when manually making requests. Instead, we keep the connection open for as long as possible and hope that the server will close.

- Converting the byte stream to content. Rules for translating the message body from [u8] to String (or perhaps an image, video, or some other content) are handled as part of the protocol. This can be tedious to handle manually as HTTP allows content to be compressed into several methods and encoded into several plain text formats.
- *Inserting or omitting port numbers.* HTTP defaults to port 80. A library that is tailored for HTTP, such as request, allows you to omit port numbers. When we're building requests by hand with generic TCP crates, however, we need to be explicit.
- Resolving the IP addresses. The TCP protocol doesn't actually know about domain names like www.rustinaction.com, for example. The library resolves the IP address for www.rustinaction.com on our behalf.

8.3 Trait objects

This section describes trait objects in detail. You will also develop the world's next best-selling fantasy role-playing game—the rpg project. If you would like to focus on networking, feel free to skip ahead to section 8.4.

There is a reasonable amount of jargon in the next several paragraphs. Brace your-self. You'll do fine. Let's start by introducing trait objects by what they achieve and what they do, rather than focusing on what they are.

8.3.1 What do trait objects enable?

While trait objects have several uses, they are immediately helpful by allowing you to create containers of multiple types. Although players of our role-playing game can choose different races, and each race is defined in its own struct, you'll want to treat those as a single type. A Vec<T> won't work here because we can't easily have types T, U, and V wedged into Vec<T> without introducing some type of wrapper object.

8.3.2 What is a trait object?

Trait objects add a form of *polymorphism*—the ability to share an interface between types—to Rust via *dynamic dispatch*. Trait objects are similar to generic objects. Generics offer polymorphism via *static dispatch*. Choosing between generics and type objects typically involves a trade off between disk space and time:

- Generics use more disk space with faster runtimes.
- Trait objects use less disk space but incur a small runtime overhead caused by pointer indirection.

Trait objects are *dynamically-sized types*, which means that these are always seen in the wild behind a pointer. Trait objects appear in three forms: &dyn Trait, &mut dyn Trait, and Box<dyn Trait>.¹ The primary difference between the three forms is that Box<dyn Trait> is an owned trait object, whereas the other two are borrowed.

¹ In old Rust code, you may see &Trait, and Box<Trait>. While legal syntax, these are officially deprecated. Adding dyn keyword is strongly encouraged.

Trait objects 257

8.3.3 Creating a tiny role-playing game: The rpg project

Listing 8.4 is the start of our game. Characters in the game can be one of three races: humans, elves, and dwarves. These are represented by the Human, Elf, and Dwarf structs, respectively.

Characters interact with things. Things are represented by the Thing type.² Thing is an enum that currently represents swords and trinkets. There's only one form of interaction right now: enchantment. Enchanting a thing involves calling the enchant () method:

```
character.enchant(&mut thing)
```

When enchantment is successful, thing glows brightly. When a mistake occurs, thing is transformed into a trinket. Within listing 8.4, we create a party of characters with the following syntax:

```
Although d, e, and h are different types, using the type hint &dyn Enchanter tells the compiler to treat each value as a trait object. These now all have the same type.

Although d, e, and h are different types, using the type hint &dyn Enchanter tells the compiler to treat each value as a trait object. These now all have the same type.

Although d, e, and h are different types, using the type hint &dyn Enchanter tells the compiler to treat each value as a trait object. These now all have the same type.
```

Casting the spell involves choosing a spellcaster. We make use of the rand crate for that:

```
58 let spellcaster = party.choose(&mut rand::thread_rng()).unwrap();
59 spellcaster.enchant(&mut it)
```

The choose() method originates from the rand::seq::SliceRandom trait that is brought into scope in listing 8.4. One of the party is chosen at random. The party then attempts to enchant the object it. Compiling and running listing 8.4 results in a variation of this:

```
$ cargo run
...
    Compiling rpg v0.1.0 (/rust-in-action/code/ch8/ch8-rpg)
    Finished dev [unoptimized + debuginfo] target(s) in 2.13s
    Running `target/debug/rpg`
Human mutters incoherently. The Sword glows brightly.

$ target/debug/rpg

Elf mutters incoherently. The Sword fizzes, then turns into a worthless
    trinket.
```

The following listing shows the metadata for our fantasy role-playing game. The source code for the rpg project is in ch8/ch8-rpg/Cargo.toml.

_

² Naming is hard.

Listing 8.3 Crate metadata for the rpg project

```
[package]
name = "rpg"
version = "0.1.0"
authors = ["Tim McNamara <author@rustinaction.com>"]
edition = "2018"

[dependencies]
rand = "0.7"
```

Listing 8.4 provides an example of using a trait object to enable a container to hold several types. You'll find its source in ch8/ch8-rpg/src/main.rs.

Listing 8.4 Using the trait object &dyn Enchanter

```
1 use rand;
 2 use rand::seq::SliceRandom;
 3 use rand::Rng;
 5 #[derive(Debug)]
 6 struct Dwarf {}
 7
 8 #[derive(Debug)]
 9 struct Elf {}
11 #[derive(Debug)]
12 struct Human {}
13
14 # [derive (Debug)]
15 enum Thing {
16
     Sword,
17
     Trinket,
18 }
19
20 trait Enchanter: std::fmt::Debug {
                                                              gen bool() generates a
    fn competency(&self) -> f64;
21
                                                              Boolean value, where true
22
                                                              occurs in proportion to its
23
     fn enchant(&self, thing: &mut Thing) {
                                                              argument. For example, a
24
       let probability of success = self.competency();
                                                              value of 0.5 returns true
25
       let spell is successful = rand::thread rng()
                                                              50% of the time.
26
          .gen_bool(probability_of_success);
27
28
       print!("{:?} mutters incoherently. ", self);
29
       if spell is successful {
30
         println!("The {:?} glows brightly.", thing);
31
       } else {
         println!("The {:?} fizzes, \
33
                 then turns into a worthless trinket.", thing);
34
          *thing = Thing::Trinket {};
       }
35
36
37 }
38
```

Trait objects 259

```
39 impl Enchanter for Dwarf {
40 fn competency(&self) -> f64 {
41
     0.5
                                           Dwarves are poor
42
     }
                                           spellcasters, and their
43 }
                                          spells regularly fail.
44 impl Enchanter for Elf {
45 fn competency(&self) -> f64 {
46

60
    let h = Human \{\};
                                                          Enchanter trait.
62
   let party: Vec<&dyn Enchanter> = vec![&d, &h, &e];
     let spellcaster = party.choose(&mut rand::thread rng()).unwrap();
64
65
     spellcaster.enchant(&mut it);
66 }
```

Trait objects are a powerful construct in the language. In a sense, they provide a way to navigate Rust's rigid type system. As you learn about this feature in more detail, you will encounter some jargon. For example, trait objects are a form of *type erasure*. The compiler does not have access to the original type during the call to enchant ().

Trait vs. type

One of the frustrating things about Rust's syntax for beginners is that trait objects and type parameters look similar. But types and traits are used in different places. For example, consider these two lines:

```
use rand::Rng;
use rand::rngs::ThreadRng;
```

Although these both have something to do with random number generators, they're quite different. rand::Rng is a trait; rand::rngs::ThreadRng is a struct. Trait objects make this distinction harder.

When used as a function argument and in similar places, the form &dyn Rng is a reference to something that implements the Rng trait, whereas &ThreadRng is a reference to a value of ThreadRng. With time, the distinction between traits and types becomes easier to grasp. Here's some common use cases for trait objects:

(continued)

- Creating collections of heterogeneous objects.
- Returning a value. Trait objects enable functions to return multiple concrete types.
- Supporting dynamic dispatch, whereby the function that is called is determined at runtime rather than at compile time.

Before the Rust 2018 edition, the situation was even more confusing. The dyn keyword did not exist. This meant that context was needed to decide between &Rng and &ThreadRng.

Trait objects are not objects in the sense that an object-oriented programmer would understand. They're perhaps closer to a mixin class. Trait objects don't exist on their own; they are agents of some other type.

An alternative analogy would be a singleton object that is delegated with some authority by another concrete type. In listing 8.4, the &Enchanter is delegated to act on behalf of three concrete types.

8.4 TCP

Dropping down from HTTP, we encounter TCP (Transmission Control Protocol). Rust's standard library provides us with cross-platform tools for making TCP requests. Let's use those. The file structure for listing 8.6, which creates an HTTP GET request, is provided here:

The following listing shows the metadata for listing 8.6. You'll find the source for this listing in ch8/ch8-stdlib/Cargo.toml.

Listing 8.5 Project metadata for listing 8.6

```
[package]
name = "ch8-stdlib"
version = "0.1.0"
authors = ["Tim McNamara <author@rustinaction.com>"]
edition = "2018"
[dependencies]
```

The next listing shows how to use the Rust standard library to construct an HTTP GET request with std::net::TcpStream. The source for this listing is in ch8/ch8-stdlib/src/main.rs.

TCP 261

Listing 8.6 Constructing an HTTP GET request

```
Explicitly specifying the
 1 use std::io::prelude::*;
                                                           port (80) is required.
 2 use std::net::TcpStream;
                                                           TcpStream does not know
                                                           that this will become a
 4 fn main() -> std::io::Result<()> {
                                                          HTTP request.
     let host = "www.rustinaction.com:80";
 6
 7
     let mut conn =
 8
       TcpStream::connect(host)?;
                                                   In many networking
 9
                                                   protocols, \r\n signifies
10
     conn.write all(b"GET / HTTP/1.0")?;
                                                   a new line.
     conn.write all(b"\r\n")?;
11
12
13
     conn.write all(b"Host: www.rustinaction.com")?;
14
     conn.write all(b"\r\n\r\n")?;
                                                            Two blank new
15
                                                            lines signify end
16
     std::io::copy(
                                       std::io::copy()
                                                            of request
17
      &mut conn,
                                       streams bytes
18
       &mut std::io::stdout()
                                       from a Reader
                                       to a Writer.
19
    )?;
20
21
     Ok(())
22 }
```

Some remarks about listing 8.6:

- On line 10, we specify HTTP 1.0. Using this version of HTTP ensures that the connection is closed when the server sends its response. HTTP 1.0, however, does not support "keep alive" requests. Specifying HTTP 1.1 actually confuses this code as the server will refuse to close the connection until it has received another request, and the client will never send one.
- On line 13, we include the hostname. This may feel redundant given that we used that exact hostname when we connected on lines 7–8. However, one should remembers that the connection is established over IP, which does not have host names. When TcpStream::connect() connects to the server, it only uses an IP address. Adding the Host HTTP header allows us to inject that information back into the context.

8.4.1 What is a port number?

Port numbers are purely virtual. They are simply u16 values. Port numbers allow a single IP address to host multiple services.

8.4.2 Converting a hostname to an IP address

So far, we've provided the hostname www.rustinaction.com to Rust. But to send messages over the internet, the IP (internet protocol) address is required. TCP knows nothing about domain names. To convert a domain name to an IP address, we rely on the Domain Name System (DNS) and its process called *domain name resolution*.

We're able to resolve names by asking a server, which can recursively ask other servers. DNS requests can be made over TCP, including encryption with TLS, but are also sent over UDP (User Datagram Protocol). We'll use DNS here because it's more useful for learning purposes.

To explain how the translation from a domain name to an IP address works, we'll create a small application that does the translation. We'll call the application *resolve*. You'll find its source code in listing 8.9. The application makes use of public DNS services, but you can easily add your own with the -s argument.

Public DNS providers

At the time of writing, several companies provide DNS servers for public use. Any of the IP addresses listed here should offer roughly equivalent service:

- 1.1.1.1 and 1.0.0.1 by Cloudflare
- 8.8.8.8 and 8.8.4.4. by Google
- 9.9.9.9 by Quad9 (founded by IBM)
- 64.6.64.6 and 64.6.65.6 by VeriSign

Our resolve application only understands a small portion of DNS protocol, but that portion is sufficient for our purposes. The project makes use of an external crate, trust-dns, to perform the hard work. The trust-dns crate implements RFC 1035, which defines DNS and several later RFCs quite faithfully using terminology derived from it. Table 8.1 outlines some of the terms that are useful to understand.

Table 8.1 Terms that are used in RFC 1035, the trust_dns crate, and listing 8.9, and how these interlink

Term	Definition	Representation in code
Domain name	A domain name is almost what you probably think of when you use the term <i>domain name</i> in your everyday language.	Defined in trust_dns::domain::Name pub struct Name { is_fqdn: bool, labels: Vec <label>,</label>
The technical definition includes some special cases such as the root domain, which is encoded as a single dot, and domain names that need to be case-insensitive.	fqdn stands for fully- qualified domain name.	

TCP 263

Table 8.1 Terms that are used in RFC 1035, the trust_dns crate, and listing 8.9, and how these interlink (continued)

Term	Definition	Representation in code
Message	A message is a container for both requests to DNS servers (called queries) and responses back to clients (called answers). Messages must contain a header, but other fields are not required. A Message struct represents this and includes several Vec <t> fields. These do not need to be wrapped in Option to represent missing values as their length can be 0.</t>	Defined in trust_dns::domain::Name struct Message { header: Header, queries: Vec <query>, answers: Vec<record>, name_servers: Vec<record>, additionals: Vec<record>, sig0: Vec<record>, edns: Option<edns>, } edns indicates whether the message includes extended DNS. sig0, a cryptographically signed record, verifies the message's integrity. It is defined in RFC 2535.</edns></record></record></record></record></query>
Message type	A message type identifies the message as a query or as an answer. Queries can also be updates, which are functionality that our code ignores.	<pre>Defined in trust_dns::op::MessageType pub enum MessageType { Query, Response, }</pre>
Message ID	A number that is used for senders to link queries and answers.	u16
Resource record type	The resource record type refers to the DNS codes that you've probably encountered if you've ever configured a domain name. Of note is how trust_dns handles invalid codes. The RecordType enum contains an Unknown (u16) variant that can be used for codes that it doesn't understand.	Defined in trust_dns::rr::record_type::RecordType pub enum RecordType { A, AAAA, ANAME, ANY, // Unknown(u16), ZERO, }
Query	A Query struct holds the domain name and the record type that we're seeking the DNS details for. These traits also describe the DNS class and allow queries to distinguish between messages sent over the internet from other transport protocols.	<pre>Defined in trust_dns::op::Query pub struct Query { name: Name, query_type: RecordType, query_class: DNSClass, }</pre>

Table 8.1	Terms that are used in RFC 1035, the trust_dns crate, and listing 8.9, and how these			
interlink (continued)				

Term	Definition	Representation in code
Opcode	An OpCode enum is, in some sense, a subtype of Message-Type. This is an extensibility mechanism that allows future functionality. For example, RFC 1035 defines the Query and Status opcodes but others were defined later. The Notify and Update opcodes are defined by RFC 1996 and RFC 2136, respectively.	<pre>Defined in trust_dns::op::OpCode pub enum OpCode { Query, Status, Notify, Update, }</pre>

An unfortunate consequence of the protocol, which I suppose is a consequence of reality, is that there are many options, types, and subtypes involved. Listing 8.7, an excerpt from listing 8.9, shows the process of constructing a message that asks, "Dear DNS server, what is the IPv4 address for domain_name?" The listing constructs the DNS message, whereas the trust-dns crate requests an IPv4 address for domain_name.

Listing 8.7 Constructing a DNS message in Rust

```
A Message is a container for
                       queries (or answers).
                                              Generates a random
                                              ul6 number
35 let mut msg = Message::new();
36 msq
                                                   Multiple queries can be
37 .set id(rand::random::<u16>()) <---
                                                   included in the same
38 .set_message_type(MessageType::Query)
                                                 message.
39 .add_query(
       Query::query(domain name, RecordType::A)
                                                                 The equivalent
41 )
                                                                 type for IPv6
                                             Requests that the
42 .set_op_code(OpCode::Query)
                                                                addresses is
                                             DNS server asks
   .set recursion desired(true);
                                                                AAAA.
                                             other DNS servers
                                             if it doesn't know
```

We're now in a position where we can meaningfully inspect the code. It has the following structure:

- Parses command-line arguments
- Builds a DNS message using trust_dns types
- Converts the structured data into a stream of bytes
- Sends those bytes across the wire

After that, we need to accept the response from the server, decode the incoming bytes, and print the result. Error handling remains relatively ugly, with many calls to unwrap() and expect(). We'll address that problem shortly in section 8.5. The end process is a command-line application that's quite simple.

TCP 265

Running our resolve application involves little ceremony. Given a domain name, it provides an IP address:

```
$ resolve www.rustinaction.com 35.185.44.232
```

Listings 8.8 and 8.9 are the project's source code. While you are experimenting with the project, you may want to use some features of cargo run to speed up your process:

```
$ cargo run -q -- www.rustinaction.com
35.185.44.232

Sends arguments to the right of -- to the executable it compiles. The -q option mutes any intermediate output.
```

To compile the resolve application from the official source code repository, execute these commands in the console:

```
$ git clone https://github.com/rust-in-action/code rust-in-action
Cloning into 'rust-in-action'...

$ cd rust-in-action/ch8/ch8-resolve
$ cargo run -q -- www.rustinaction.com
35.185.44.232

| It may take a while to download the project's dependencies and compile the code. The -q flag mutes intermediate output. Adding two dashes (--) sends further arguments to the compiled executable.
```

To compile and build from scratch, follow these instructions to establish the project structure:

1 At the command-line, enter these commands:

- 2 Once the structure has been established, you check that your Cargo.toml matches listing 8.8, available in ch8/ch8-resolve/Cargo.toml.
- 3 Replace the contents of src/main.rs with listing 8.9. It is available from ch8/ch8-resolve/src/main.rs.

The following snippet provides a view of how the files of the project and the listings are interlinked:

```

                                                                     Specifies that this is a
43
     let mut encoder =
                                                                     DNS query, not a DNS
44
       BinEncoder::new(&mut request as bytes);
                                                                     answer. Both have the
45
     msg.emit(&mut encoder).unwrap();
                                                                     same representation
46
                                                                     over the wire, but not
47
     let localhost = UdpSocket::bind("0.0.0.0:0")
                                                           <1
                                                                     in Rust's type system.
       .expect("cannot bind to local socket");
48
49
     let timeout = Duration::from secs(3);
                                                                   Converts the Message
50
     localhost.set read timeout(Some(timeout)).unwrap();
                                                                   type into raw bytes
51
     localhost.set nonblocking(false).unwrap();
                                                                   with BinEncoder
52
53
     let amt = localhost
                                                                 0.0.0.0:0 means listen to
54
        .send to(&request as bytes, dns server)
                                                                 all addresses on a random
55
        .expect("socket misconfigured");
                                                                 port. The OS selects the
56
                                                                 actual port.
57
     let ( amt, remote) = localhost
58
        .recv from(&mut response as bytes)
59
        .expect("timeout reached");
60
61
     let dns_message = Message::from_vec(&response_as_bytes)
62
        .expect("unable to parse response");
63
64
     for answer in dns message.answers() {
       if answer.record_type() == RecordType::A {
65
66
         let resource = answer.rdata();
67
         let ip = resource
68
            .to ip addr()
            .expect("invalid IP address received");
69
70
          println!("{}", ip.to string());
71
72
     }
73 }
```

Listing 8.9 includes some business logic that deserves explaining. Lines 30–33, repeated here, use two forms of initializing a Vec<u8>. Why?

```
30 let mut request_as_bytes: Vec<u8> =
31    Vec::with_capacity(512);
32 let mut response_as_bytes: Vec<u8> =
33    vec![0; 512];
```

Each form creates a subtly different outcome:

- Vec::with capacity (512) creates a Vec<T> with length 0 and capacity 512.
- vec! [0; 512] creates a Vec<T> with length 512 and capacity 512.

The underlying array looks the same, but the difference in length is significant. Within the call to recv_from() at line 58, the trust-dns crate includes a check that response_as_bytes has sufficient space. That check uses the length field, which results in a crash. Knowing how to wriggle around with initialization can be handy for satisfying an APIs' expectations.

How DNS supports connections within UDP

UDP does not have a notion of long-lived connections. Unlike TCP, all messages are short-lived and one-way. Put another way, UDP does not support two-way (*duplex*) communications. But DNS requires a response to be sent from the DNS server back to the client.

To enable two-way communications within UDP, both parties must act as clients and servers, depending on context. That context is defined by the protocol built on top of UDP. Within DNS, the client becomes a DNS server to receive the server's reply. The following table provides a flow chart of the process.

Stage	DNS client role	DNS server role
Request sent from DNS client	UDP client	UDP server
Reply sent from DNS server	UDP server	UDP client

It's time to recap. Our overall task in this section was to make HTTP requests. HTTP is built on TCP. Because we only had a domain name (www.rustinaction.com) when we made the request, we needed to use DNS. DNS is primarily delivered over UDP, so we needed to take a diversion and learn about UDP.

Now it's almost time to return to TCP. Before we're able to do that, though, we need to learn how to combine error types that emerge from multiple dependencies.

8.5 Ergonomic error handling for libraries

Rust's error handling is safe and sophisticated. However, it offers a few challenges. When a function incorporates Result types from two upstream crates, the ? operator no longer works because it only understands a single type. This proves to be important when we refactor our domain resolution code to work alongside our TCP code. This section discusses some of those challenges as well as strategies for managing them.

8.5.1 Issue: Unable to return multiple error types

Returning a Result<T, E> works great when there is a single error type E. But things become more complicated when we want to work with multiple error types.

TIP For single files, compile the code with rustc <filename> rather than using cargo build. For example, if a file is named io-error.rs, then the shell command is rustc io-error.rs && ./io-error[.exe].

To start, let's look at a small example that covers the easy case of a single error type. We'll try to open a file that does not exist. When run, listing 8.10 prints a short message in Rust syntax:

```
$ rustc ch8/misc/io-error.rs && ./io-error
Error: Os { code: 2, kind: NotFound, message: "No such file or directory" }
```

We won't win any awards for user experience here, but we get a chance to learn a new language feature. The following listing provides the code that produces a single error type. You'll find its source in ch8/misc/io-error.rs.

Listing 8.10 A Rust program that always produces an I/O error

```
1 use std::fs::File;
2
3 fn main() -> Result<(), std::io::Error> {
4    let _f = File::open("invisible.txt")?;
5
6    Ok(())
7 }
```

Now, let's introduce another error type into main(). The next listing produces a compiler error, but we'll work through some options to get the code to compile. The code for this listing is in ch8/misc/multierror.rs.

Listing 8.11 A function that attempts to return multiple Result types

```
1 use std::fs::File;
2 use std::net::Ipv6Addr;
                                                       File::open()
                                                       returns Result < (),
4 fn main() -> Result<(), std::io::Error> {
                                                       std::io::Error>.
    let f = File::open("invisible.txt")?;
6
7 let localhost = "::1"
                                  "".parse::<Ipv6Addr>() returns Result<Ipv6Addr,
     .parse::<Ipv6Addr>()?;
                                 std::net::AddrParseError>.
8
9
10 Ok(())
11 }
```

To compile listing 8.11, enter the ch8/misc directory and use rustc. This produces quite a stern, yet helpful, error message:

```
$ rustc multierror.rs
error[E0277]: `?` couldn't convert the error to `std::io::Error`
 --> multierror.rs:8:25
4 | fn main() -> Result<(), std::io::Error> {
                ----- expected `std::io::Error`
                                          because of this
      .parse::<Ipv6Addr>()?;
                          ^ the trait `From<AddrParseError>`
                            is not implemented for `std::io::Error`
 = note: the question mark operation (`?`) implicitly performs a
         conversion on the error value using the `From` trait
  = help: the following implementations were found:
           <std::io::Error as From<ErrorKind>>
           <std::io::Error as From<IntoInnerError<W>>>
           <std::io::Error as From<NulError>>
  = note: required by `from`
error: aborting due to previous error
For more information about this error, try `rustc --explain E0277`.
```

The error message can be difficult to interpret if you don't know what the question mark operator (?) is doing. Why are there multiple messages about std::convert::From? Well, the ? operator is syntactic sugar for the try! macro. try! performs two functions:

- When it detects Ok (value), the expression evaluates to value.
- When Err (err) occurs, try!/? returns early after attempting to convert err to the error type defined in the calling function.

In Rust-like pseudocode, the try! macro could be defined as

```
Uses val when an
                                                             Converts err to the
macro try {
                                        expression matches
                                                              outer function's error
 match expression {
                                       Result::Ok(val)
                                                              type when it matches
    Result::Ok(val) => val,
                                                               Result::Err(err) and
    Result::Err(err) => {
                                                              then returns early
      let converted = convert::From::from(err);
      return Result::Err(converted); <---
                                                 Returns from the
                                                  calling function, not
  });
                                                 the try! macro itself
```

Looking at listing 8.11 again, we can see the try! macro in action as ?:

```
file::open() returns

file::open() returns

std::io::Error, so no
conversion is necessary.

file::open() returns
std::io::Error, so no
conversion is necessary.

file::open() returns
std::io::Error, so no
conversion is necessary.

file::open() returns
std::io::Error, so no
conversion is necessary.
```

```
9
10 Ok(())
11 }
```

In addition to saving you from needing to use explicit pattern matching to extract the value or return an error, the ? operator also attempts to convert its argument into an error type if required. Because the signature of main is main() ? Result<(), std::io::Error>, Rust attempts to convert the std::net::AddrParseError produced by parse::<Ipv6Addr>() into a std::io::Error. Don't worry, though; we can fix this! Earlier, in section 8.3, we introduced trait objects. Now we'll be able to put those to good use.

Using Box<dyn Error> as the error variant in the main() function allows us to progress. The dyn keyword is short for *dynamic*, implying that there is a runtime cost for this flexibility. Running listing 8.12 produces this output:

```
$ rustc ch8/misc/traiterror.rs && ./traiterror
Error: Os { code: 2, kind: NotFound, message: "No such file or directory" }
```

I suppose it's a limited form of progress, but progress nonetheless. We've circled back to the error we started with. But we've passed through the compiler error, which is what we wanted.

Going forward, let's look at listing 8.12. It implements a trait object in a return value to simplify error handling when errors originate from multiple upstream crates. You can find the source for this listing in ch8/misc/traiterror.rs.

Listing 8.12 Using a trait object in a return value

```
1 use std::fs::File;
 2 use std::error::Error;
                                                           A trait object, Box<dyn
 3 use std::net::Ipv6Addr;
                                                           Error>, represents any type
                                                           that implements Error.
 5 fn main() -> Result<(), Box<dyn Error>> {
 7
     let f = File::open("invisible.txt")?;
                                                           Error type is
                                                           std::io::Error
 9
   let localhost = "::1"
10
   .parse::<Ipv6Addr>()?
                                          Error type is
11
                                           std::net::AddrParseError
12
    Ok(())
13 }
```

Wrapping trait objects in Box is necessary because their size (in bytes on the stack) is unknown at compile time. In the case of listing 8.12, the trait object might originate from either File::open() or "::1".parse(). What actually happens depends on the circumstances encountered at runtime. A Box has a known size on the stack. Its raison d'être is to point to things that don't, such as trait objects.

8.5.2 Wrapping downstream errors by defining our own error type

The problem that we are attempting to solve is that each of our dependencies defines its own error type. Multiple error types in one function prevent returning Result. The first strategy we looked at was to use trait objects, but trait objects have a potentially significant downside.

Using trait objects is also known as *type erasure*. Rust is no longer aware that an error has originated upstream. Using Box<dyn Error> as the error variant of a Result means that the upstream error types are, in a sense, lost. The original errors are now converted to exactly the same type.

It is possible to retain the upstream errors, but this requires more work on our behalf. We need to bundle upstream errors in our own type. When the upstream errors are needed later (say, for reporting errors to the user), it's possible to extract these with pattern matching. Here is the process:

- 1 Define an enum that includes the upstream errors as variants.
- 2 Annotate the enum with #[derive(Debug)].
- 3 Implement Display.
- 4 Implement Error, which almost comes for free because we have implemented Debug and Display.
- 5 Use map_err() in your code to convert the upstream error to your omnibus error type.

NOTE You haven't previously encountered the map_err() function. We'll explain what it does when we get there later in this section.

It's possible to stop with the previous steps, but there's an optional extra step that improves the ergonomics. We need to implement std::convert::From to remove the need to call map_err(). To begin, let's start back with listing 8.11, where we know that the code fails:

```
use std::fs::File;
use std::net::Ipv6Addr;
fn main() -> Result<(), std::io::Error> {
  let _f = File::open("invisible.txt")?;
  let _localhost = "::1"
    .parse::<Ipv6Addr>()?;
  Ok(())
}
```

This code fails because "".parse::<Ipv6Addr>() does not return a std::io::Error. What we want to end up with is code that looks a little more like the following listing.

Listing 8.13 Hypothetical example of the kind of code we want to write

```
1 use std::fs::File;
 2 use std::io::Error;
                                      Brings upstream errors
 3 use std::net::AddrParseError;
                                    into local scope
 4 use std::net::Ipv6Addr;
 6 enum UpstreamError{
 7
   IO(std::io::Error),
 8 Parsing(AddrParseError),
9 }
10
11 fn main() -> Result<(), UpstreamError> {
    let f = File::open("invisible.txt")?
13
      .maybe convert to(UpstreamError);
14
15 let localhost = "::1"
16
     .parse::<Ipv6Addr>()?
      .maybe_convert_to(UpstreamError);
17
18
19 Ok(())
20 }
```

DEFINE AN ENUM THAT INCLUDES THE UPSTREAM ERRORS AS VARIANTS

The first thing to do is to return a type that can hold the upstream error types. In Rust, an enum works well. Listing 8.13 does not compile, but does do this step. We'll tidy up the imports slightly, though:

```
use std::io;
use std::net;
enum UpstreamError{
   IO(io::Error),
   Parsing(net::AddrParseError),
}
```

ANNOTATE THE ENUM WITH #[DERIVE(DEBUG)]

The next change is easy. It's a single-line change—the best kind of change. To annotate the enum, we'll add # [derive (Debug)], as the following shows:

```
use std::io;
use std::net;
#[derive(Debug)]
enum UpstreamError{
   IO(io::Error),
   Parsing(net::AddrParseError),
}
```

IMPLEMENT STD::FMT::DISPLAY

We'll cheat slightly and implement Display by simply using Debug. We know that this is available to us because errors must define Debug. Here's the updated code:

```
use std::fmt;
use std::io;
use std::net;

#[derive(Debug)]
enum UpstreamError{
    IO(io::Error),
    Parsing(net::AddrParseError),
}

impl fmt::Display for UpstreamError {
    fn fmt(&self, f: &mut fmt::Formatter<'_>) -> fmt::Result {
        write!(f, "{:?}", self)
    }

    Implements Display in terms
    of Debug via the "{:?}" syntax
```

IMPLEMENT STD::ERROR::ERROR

Here's another easy change. To end up with the kind of code that we'd like to write, let's make the following change:

```
use std::error;
                           Brings the
use std::fmt;
                            std::error::Error trait
use std::io;
                           into local scope
use std::net;
#[derive(Debug)]
enum UpstreamError{
 IO(io::Error),
  Parsing (net::AddrParseError),
impl fmt::Display for UpstreamError {
  fn fmt(&self, f: &mut fmt::Formatter<' >) -> fmt::Result {
    write!(f, "{:?}", self)
                                                     Defers to default method
}
                                                     implementations. The compiler
                                                     will fill in the blanks.
impl error::Error for UpstreamError { }
```

The impl block is—well, we can rely on default implementations provided by the compiler—especially terse. Because there are default implementations of every method defined by std::error::Error, we can ask the compiler to do all of the work for us.

USE MAP_ERR()

The next fix is to add map_err() to our code to convert the upstream error to the omnibus error type. Back at listing 8.13, we wanted to have a main() that looks like this:

```
fn main() -> Result<(), UpstreamError> {
  let _f = File::open("invisible.txt")?
    .maybe_convert_to(UpstreamError);

let _localhost = "::1"
    .parse::<Ipv6Addr>()?
```

```
.maybe_convert_to(UpstreamError);
Ok(())
}
I can't offer you that. I can, however, give you this:
fn main() -> Result<(), UpstreamError> {
  let _f = File::open("invisible.txt")
    .map_err(UpstreamError::IO)?;

let _localhost = "::1"
    .parse::<Ipv6Addr>()
    .map_err(UpstreamError::Parsing)?;

Ok(())
```

}

This new code works! Here's how. The map_err() function maps an error to a function. (Variants of our UpstreamError enum can be used as functions here.) Note that the ? operator needs to be at the end. Otherwise, the function can return before the code has a chance to convert the error.

Listing 8.14 provides the new code. When run, it produces this message to the console:

```
$ rustc ch8/misc/wraperror.rs && ./wraperror
Error: IO(Os { code: 2, kind: NotFound, message: "No such file or directory" })
```

To retain type safety, we can use the new code in the following listing. You'll find its source in ch8/misc/wraperror.rs.

Listing 8.14 Wrapping upstream errors in our own type

```
1 use std::io;
 2 use std::fmt;
 3 use std::net;
 4 use std::fs::File;
 5 use std::net::Ipv6Addr;
 7 #[derive(Debug)]
 8 enum UpstreamError{
   IO(io::Error),
 9
10 Parsing(net::AddrParseError),
11 }
12
13 impl fmt::Display for UpstreamError {
fn fmt(&self, f: &mut fmt::Formatter<' >) -> fmt::Result {
       write!(f, "{:?}", self)
15
16
     }
17 }
18
19 impl error::Error for UpstreamError { }
```

```
20
21 fn main() -> Result<(), UpstreamError> {
22  let _f = File::open("invisible.txt")
23  .map_err(UpstreamError::IO)?;
24
25  let _localhost = "::1"
26  .parse::<Ipv6Addr>()
27  .map_err(UpstreamError::Parsing)?;
28
29  Ok(())
30 }
```

It's also possible to remove the calls to map_err(). But to enable that, we need to implement From.

IMPLEMENT STD::CONVERT::FROM TO REMOVE THE NEED TO CALL MAP_ERR()

The std::convert::From trait has a single required method, from(). We need two impl blocks to enable our two upstream error types to be convertible. The following snippet shows how:

```
impl From<io::Error> for UpstreamError {
   fn from(error: io::Error) -> Self {
      UpstreamError::IO(error)
   }
}
impl From<net::AddrParseError> for UpstreamError {
   fn from(error: net::AddrParseError) -> Self {
      UpstreamError::Parsing(error)
   }
}
```

Now the main() function returns to a simple form of itself:

```
fn main() -> Result<(), UpstreamError> {
  let _f = File::open("invisible.txt")?;
  let _localhost = "::1".parse::<Ipv6Addr>()?;
  Ok(())
}
```

The full code listing is provided in listing 8.15. Implementing From places the burden of extra syntax on the library writer. It results in a much easier experience when using your crate, simplifying its use by downstream programmers. You'll find the source for this listing in ch8/misc/wraperror2.rs.

Listing 8.15 Implementing std::convert::From for our wrapper error type

```
1 use std::io;
2 use std::fmt;
3 use std::net;
```

MAC addresses 277

```
4 use std::fs::File;
 5 use std::net::Ipv6Addr;
 7 #[derive(Debug)]
 8 enum UpstreamError{
   IO(io::Error),
10 Parsing(net::AddrParseError),
11 }
12
13 impl fmt::Display for UpstreamError {
fn fmt(&self, f: &mut fmt::Formatter<' >) -> fmt::Result {
     write!(f, "{:?}", self)
                                                                  1((CO20-1))
16
17 }
18
19 impl error::Error for UpstreamError { }
21 impl From<io::Error> for UpstreamError {
22 fn from(error: io::Error) -> Self {
       UpstreamError::IO(error)
2.3
24
25 }
26
27 impl From<net::AddrParseError> for UpstreamError {
     fn from(error: net::AddrParseError) -> Self {
29
     UpstreamError::Parsing(error)
30
31 }
32
33 fn main() -> Result<(), UpstreamError> {
34 let f = File::open("invisible.txt")?;
     let _localhost = "::1".parse::<Ipv6Addr>()?;
36
37
   Ok(())
38 }
```

8.5.3 Cheating with unwrap() and expect()

The final approach for dealing with multiple error types is to use unwrap() and expect(). Now that we have the tools to handle multiple error types in a function, we can continue our journey.

NOTE This is a reasonable approach when writing a main() function, but it isn't recommended for library authors. Your users don't want their programs to crash because of things outside of their control.

8.6 MAC addresses

Several pages ago in listing 8.9, you implemented a DNS resolver. That enabled conversions from a host name such as www.rustinaction.com to an IP address. Now we have an IP address to connect to.

The internet protocol enables devices to contact each other via their IP addresses. But that's not all. Every hardware device also includes a unique identifier that's independent of the network it's connected to. Why a second number? The answer is partially technical and partially historical.

Ethernet networking and the internet started life independently. Ethernet's focus was on local area networks (LANs). The internet was developed to enable communication between networks, and Ethernet is the addressing system understood by devices that share a physical link (or a radio link in the case of WiFi, Bluetooth, and other wireless technologies).

Perhaps a better way to express this is that MAC (short for *media access control*) addresses are used by devices that share electrons (figure 8.3). But there are a few differences:

- IP addresses are hierarchical, but MAC addresses are not. Addresses appearing close together numerically are not close together physically, or organizationally.
- MAC addresses are 48 bits (6 bytes) wide. IP addresses are 32 bits (4 bytes) wide for IPv4 and 128 bits (16 bytes) for IPv6.

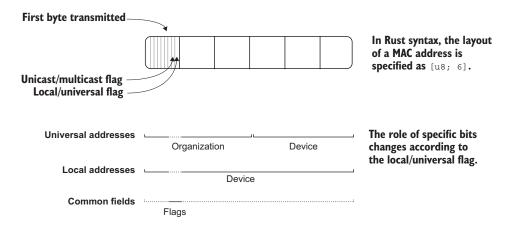

Figure 8.3 In-memory layout for MAC addresses

There are two forms of MAC addresses:

- Universally administered (or universal) addresses are set when devices are manufactured.
 Manufacturers use a prefix assigned by the IEEE Registration Authority and a scheme of their choosing for the remaining bits.
- Locally administered (or local) addresses allow devices to create their own MAC addresses without registration. When setting a device's MAC address yourself in software, you should make sure that your address is set to the local form.

MAC addresses 279

MAC addresses have two modes: *unicast* and *multicast*. The transmission behavior for these forms is identical. The distinction is made when a device makes a decision about whether to accept a frame. A *frame* is a term used by the Ethernet protocol for a byte slice at this level. Analogies to frame include a packet, wrapper, and envelope. Figure 8.4 shows this distinction.

Unicast vs. multicast MAC addresses

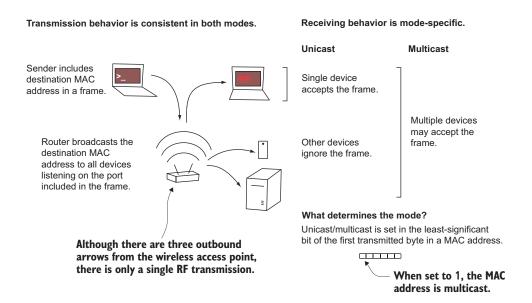

Figure 8.4 The differences between multicast and unicast MAC addresses

Unicast addresses are intended to transport information between two points that are in direct contact (say, between a laptop and a router). Wireless access points complicate matters somewhat but don't change the fundamentals. A multicast address can be accepted by multiple recipients, whereas unicast has a single recipient. The term *unicast* is somewhat misleading, though. Sending an Ethernet packet involves more than two devices. Using a unicast address alters what devices do when they receive packets but not which data is transmitted over the wire (or through the radio waves).

8.6.1 Generating MAC addresses

When we begin talking about raw TCP in section 8.8, we'll create a virtual hardware device in listing 8.22. To convince anything to talk to us, we need to learn how to assign our virtual device a MAC address. The macgen project in listing 8.17 generates

the MAC addresses for us. The following listing shows the metadata for that project. You can find its source in ch8/ch8-mac/Cargo.toml.

Listing 8.16 Crate metadata for the macgen project

```
[package]
name = "ch8-macgen"
version = "0.1.0"
authors = ["Tim McNamara <author@rustinaction.com>"]
edition = "2018"

[dependencies]
rand = "0.7"
```

The following listing shows the macgen project, our MAC address generator. The source code for this project is in the ch8/ch8-mac/src/main.rs file.

Listing 8.17 Creating macgen, a MAC address generator

```
1 extern crate rand;
 3 use rand::RngCore;
 4 use std::fmt;
 5 use std::fmt::Display;
                                         Uses the newtype pattern to
                                         wrap a bare array without
 7 #[derive(Debug)]
                                         any extra overhead
 8 struct MacAddress([u8; 6]);
10 impl Display for MacAddress {
fn fmt(&self, f: &mut fmt::Formatter<' >) -> fmt::Result {
     let octet = &self.0;
13
     write!(
14
        \{:02x\}:\{:02x\}:\{:02x\}:\{:02x\}:\{:02x\}:\{:02x\}:\{:02x\}
15
                                                            Converts each byte
       octet[0], octet[1], octet[2],
                                                            to hexadecimal
         octet[3], octet[4], octet[5]
                                                            notation
17
18
     )
19
20 }
21
22 impl MacAddress {
23 fn new() -> MacAddress {
                                                       Sets the MAC
     let mut octets: [u8; 6] = [0; 6];
                                                       address to local
     rand::thread rng().fill bytes(&mut octets);
                                                       and unicast
26
     octets[0] |= 0b_0000_0011;
     MacAddress { 0: octets }
27
28
29
30
    fn is local(&self) -> bool {
     (self.0[0] & 0b 0000 0010) == 0b 0000 0010
31
32
33
34
     fn is unicast(&self) -> bool {
35
       (self.0[0] & 0b 0000 0001) == 0b 0000 0001
```

```
36  }
37  }
38
39  fn main() {
40    let mac = MacAddress::new();
41    assert!(mac.is_local());
42    assert!(mac.is_unicast());
43    println!("mac: {}", mac);
44 }
```

The code from listing 8.17 should feel legible. Line 25 contains some relatively obscure syntax, though. octets [0] |= 0b_0000_0011 coerces the two flag bits described at figure 8.3 to a state of 1. That designates every MAC address we generate as locally assigned and unicast.

8.7 Implementing state machines with Rust's enums

Another prerequisite for handling network messages is being able to define a state machine. Our code needs to adapt to changes in connectivity.

Listing 8.22 contains a state machine, implemented with a loop, a match, and a Rust enum. Because of Rust's expression-based nature, control flow operators also return values. Every time around the loop, the state is mutated in place. The following listing shows the pseudocode for how a repeated match on a enum works together.

Listing 8.18 Pseudocode for a state machine implementation

```
enum HttpState {
   Connect,
   Request,
   Response,
}
loop {
    state = match state {
        HttpState::Connect if !socket.is_active() => {
            socket.connect();
           HttpState::Request
        HttpState::Request if socket.may send() => {
            socket.send(data);
            HttpState::Response
        }
        HttpState::Response if socket.can recv() => {
            received = socket.recv();
            HttpState::Response
        HttpState::Response if !socket.may_recv() => {
           break;
```

```
_ => state,
}
}
```

More advanced methods to implement finite state machines do exist. This is the simplest, however. We'll make use of it in listing 8.22. Making use of an enum embeds the state machine's transitions into the type system itself.

But we're still at a level that is far too high! To dig deeper, we're going to need to get some assistance from the OS.

8.8 Raw TCP

Integrating with the raw TCP packets typically requires root/superuser access. The OS starts to get quite grumpy when an unauthorized user asks to make raw network requests. We can get around this (on Linux) by creating a proxy device that non-super users are allowed to communicate with directly.

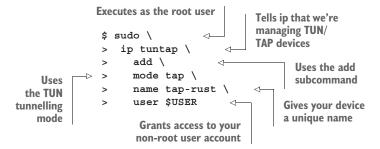

Don't have Linux?

If you're running another OS, there are many virtualization options available. Here are a few:

- The Multipass project (https://multipass.run/) provides fast Ubuntu virtual machines on macOS and Windows hosts.
- WSL, the Windows Subsystem for Linux (https://docs.microsoft.com/en-us/windows/wsl/about), is another option to look into.
- Oracle VirtualBox (https://www.virtualbox.org/) is an open source project with excellent support for many host operating systems.

8.9 Creating a virtual networking device

To proceed with this section, you will need to create virtual networking hardware. Using virtual hardware provides more control to freely assign IP and MAC addresses. It also avoids changing your hardware settings, which could affect its ability to connect to the network. To create a TAP device called tap-rust, execute the following command in your Linux console:

"Raw" HTTP 283

When successful, ip prints no output. To confirm that our tap-rust device was added, we can use the ip tuntap list subcommand as in the following snippet. When executed, you should see the tap-rust device in the list of devices in the output:

```
$ ip tuntap list
tap-rust: tap persist user
```

Now that we have created a networking device, we also need to allocate an IP address for it and tell our system to forward packets to it. The following shows the commands to enable this functionality:

```
Establishes a network device
                called tap-rust and activates it
                                                                     Assigns the IP address
                                                                     192.168.42.100 to
$ sudo ip link set tap-rust up
                                                                     the device
$ sudo ip addr add 192.168.42.100/24 dev tap-rust
$ sudo iptables \
                                   Enables internet packets to reach the source IP
   -t nat\
                                   address mask (-s 192.168.42.100/24) by appending
    -A POSTROUTING \
                                   a rule (-A POSTROUTING) that dynamically maps IP
    -s 192.168.42.0/24 \
                                  addresses to a device (-j MASQUERADE)
    - j MASQUERADE
                                                      Instructs the kernel to enable
                                                     IPv4 packet forwarding
$ sudo sysctl net.ipv4.ip forward=1
```

The following shows how to remove the device (once you have completed this chapter) by using del rather than add:

```
$ sudo ip tuntap del mode tap name tap-rust
```

8.10 "Raw" HTTP

We should now have all the knowledge we need to take on the challenge of using HTTP at the TCP level. The mget project (mget is short for *manually get*) spans listings 8.20–8.23. It is a large project, but you'll find it immensely satisfying to understand and build. Each file provides a different role:

- *main.rs* (*listing 8.20*)—Handles command-line parsing and weaves together the functionality provided by its peer files. This is where we combine the error types using the process outlined in section 8.5.2.
- *ethernet.rs* (*listing* 8.21)—Generates a MAC address using the logic from listing 8.17 and converts between MAC address types (defined by the smoltcp crate) and our own.
- *http.rs* (*listing 8.22*)—Carries out the work of interacting with the server to make the HTTP request.
- dns.rs (listing 8.23)—Performs DNS resolution, which converts a domain name to an IP address.

NOTE The source code for these listings (and every code listing in the book) is available from https://github.com/rust-in-action/code or https://www.manning.com/books/rust-in-action.

It's important to acknowledge that listing 8.22 was derived from the HTTP client example within the smoltcp crate itself. whitequark (https://whitequark.org/) has built an absolutely fantastic networking library. Here's the file structure for the mget project:

```
ch8-mget
Cargo.toml
src
main.rs
ethernet.rs
http.rs
dns.rs

See listing 8.19.
See listing 8.20.
See listing 8.21.
See listing 8.21.
See listing 8.22.
```

To download and run the mget project from source control, execute these commands at the command line:

```
\ git clone https://github.com/rust-in-action/code rust-in-action Cloning into 'rust-in-action'...
```

\$ cd rust-in-action/ch8/ch8-mget

Here are the project setup instructions for those readers who enjoy doing things step by step (with the output omitted).

1 Enter these commands at the command-line:

```
$ cargo new mget
$ cd mget
$ cargo install cargo-edit
$ cargo add clap@2
$ cargo add url@02
$ cargo add rand@0.7
$ cargo add trust-dns@0.16 --no-default-features
$ cargo add smoltcp@0.6 --features='proto-igmp proto-ipv4 verbose log'
```

- 2 Check that your project's Cargo.toml matches listing 8.19.
- 3 Within the src directory, listing 8.20 becomes main.rs, listing 8.21 becomes ethernet.rs, listing 8.22 becomes http.rs, and listing 8.23 becomes dns.rs.

"Raw" HTTP 285

The following listing shows the metadata for mget. You'll find its source code in the ch8/ch8-mget/Cargo.toml file.

Listing 8.19 Crate metadata for mget

```
[package]
name = "mget"
version = "0.1.0"
authors = ["Tim McNamara <author@rustinaction.com>"]
edition = "2018"
                         Provides
                         command-line
                                           Selects a random
[dependencies]
                         argument parsing
                                            port number
clap = "2"
rand = "0.7"
                                              Provides a TCP
smoltcp = {
                                              implementation
 version = "0.6",
 features = ["proto-igmp", "proto-ipv4", "verbose", "log"]
trust-dns = {
 version = "0.16",
                               Enables connecting
                                to a DNS server
  default-features = false
url = "2"
                  Parses and validates URLs
```

The following listing shows the command-line parsing for our project. You'll find this source in ch8/ch8-mget/src/main.rs.

Listing 8.20 mget command-line parsing and overall coordination

```
1 use clap::{App, Arg};
 2 use smoltcp::phy::TapInterface;
 3 use url::Url;
 5 mod dns;
 6 mod ethernet;
 7 mod http;
                                             Requires a URL to
 9 fn main() {
                                           download data from
   let app = App::new("mget")
                                                                    Requires a TAP
1.0
                                                                    networking
      .about("GET a webpage, manually")
                                                                    device to
       .arg(Arg::with name("url").required(true))
12
                                                                    connect with
13
      .arg(Arg::with name("tap-device").required(true))
14
                                                Makes it possible for the user to
        Arg::with name("dns-server")
                                               select which DNS server to use
           .default value("1.1.1.1"),
16
17
                                  Parses the command-line
18
       .get matches();
19
20
     let url_text = app.value_of("url").unwrap();

mget is an ambitious project. It brings together all the threads from the chapter, is dozens of lines long, and yet is less capable than the request::get(url) call we made in listing 8.2. Hopefully it's revealed several interesting avenues for you to explore. Perhaps, surprisingly, there are several more networking layers to unwrap. Well done for making your way through a lengthy and challenging chapter.

Summary

- Networking is complicated. Standard models such as OSIs are only partially accurate.
- Trait objects allow for runtime polymorphism. Typically, programmers prefer generics because trait objects incur a small runtime cost. However, this situation is not always clear-cut. Using trait objects can reduce space because only a single version of each function needs to be compiled. Fewer functions also benefits cache coherence.
- Networking protocols are particular about which bytes are used. In general, you should prefer using &[u8] literals (b"...") over &str literals ("...") to ensure that you retain full control.
- There are three main strategies for handling multiple upstream error types within a single scope:
 - Create an internal wrapper type and implement From for each of the upstream types
 - Change the return type to make use of a trait object that implements std::
 error:Error
 - Use .unwrap() and its cousin .expect()
- Finite state machines can be elegantly modeled in Rust with an enum and a loop. At each iteration, indicate the next state by returning the appropriate enum variant.
- To enable two-way communications in UDP, each side of the conversation must be able to act as a client and a server.

Time and timekeeping

This chapter covers

- Understanding how a computer keeps time
- How operating systems represent timestamps
- Synchronizing atomic clocks with the Network Time Protocol (NTP)

In this chapter, you'll produce an NTP (Network Time Protocol) client that requests the current time from the world's network of public time servers. It's a fully functioning client that can be included in your own computer's boot process to keep it in sync with the world.

Understanding how time works within computers supports your efforts to build resilient applications. The system clock jumps both backwards and forwards in time. Knowing why this happens allows you to anticipate and prepare for that eventuality.

Your computer also contains multiple physical and virtual clocks. It takes some knowledge to understand the limitations of each and when these are appropriate. Understanding the limitations of each should foster a healthy skepticism about micro benchmarks and other time-sensitive code.

Some of the hardest software engineering involves distributed systems that need to agree on what the time is. If you have the resources of Google, then you're able to maintain a network atomic clock that provides a worldwide time synchronization of 7 ms. The closest open source alternative is CockroachDB (https://www.cockroachlabs.com/). It relies on the NTP, which can have a (worldwide) latency of approximately dozens of milliseconds. But that doesn't make it useless. When deployed within a local network, NTP allows computers to agree on the time to within a few milliseconds or less.

On the Rust side of the equation, this chapter invests lots of time interacting with the OS internals. You'll become more confident with unsafe blocks and with using raw pointers. Readers will become familiar with chrono, the de facto standard crate for high-level time and clock operations.

9.1 Background

It's easy to think that a day has 86,400 seconds ($60 \text{ s} \times 60 \text{ min} \times 24 \text{ h} = 86,400 \text{ s}$). But the earth's rotation isn't quite that perfect. The length of each day fluctuates due to tidal friction with the moon and other effects such as torque at the boundary of the earth's core and its mantle.

Software does not tolerate these imperfections. Most systems assume that most seconds have an equal duration. The mismatch presents several problems.

In 2012, a large number of services—including high profile sites such as Reddit and Mozilla's Hadoop infrastructure—stopped functioning after a leap second was added to their clocks. And, at times, clocks can go back in time (this chapter does not, however, cover time travel). Few software systems are prepared for the same time-stamp to appear twice. That makes it difficult to debug the logs. There are two options for resolving this impasse:

- *Keep the length of each second fixed.* This is good for computers but irritating for humans. Over time, "midday" drifts towards sunset or sunrise.
- Adjust the length of each year to keep the sun's position relative to noon in the same place from year to year. This is good for humans but sometimes highly irritating for computers.

In practice, we can chose both options as we do in this chapter. The world's atomic clocks use their own time zone with fixed-length seconds, called TAI. Everything else uses time zones that are periodically adjusted; these are called UTC.

TAI is used by the world's atomic clocks and maintains a fixed-length year. UTC adds leap seconds to TAI about once every 18 months. In 1972, TAI and UTC were 10 seconds apart. By 2016, they had drifted to 36 seconds apart.

In addition to the issues with earth's fickle rotational speed, the physics of your own computer make it challenging to keep accurate time. There are also (at least) two clocks running on your system. One is a battery-powered device, called the *real-time clock*. The other one is known as *system time*. System time increments itself based on hardware interrupts provided by the computer's motherboard. Somewhere in your system, a quartz crystal is oscillating rapidly.

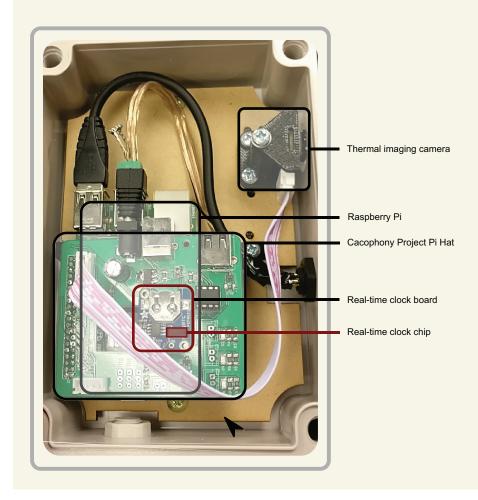

Background 295

Dealing with hardware platforms without a real-time clock

The Raspberry Pi device does not include a battery-supported, real-time clock. When the computer turns on, the system clock is set to *epoch time*. That it, it is set to the number of elapsed seconds since 1 Jan 1970. During boot, it uses the NTP to identify the current time.

What about situations where there is no network connection? This is the situation faced by the Cacophony Project (https://cacophony.org.nz/), which develops devices to support New Zealand's native bird species by applying computer vision to accurately identify pest species.

The main sensor of the device is a thermal imaging camera. Footage needs to be annotated with accurate timestamps. To enable this, the Cacophony Project team decided to add an additional real-time clock, Raspberry Pi Hat, to their custom board. The following figure shows the internals of the prototype for the Cacophony Project's automated pest detection system.

9.2 Sources of time

Computers can't look at the clock on the wall to determine what time it is. They need to figure it out by themselves. To explain how this happens, let's consider how digital clocks operate generally, then how computer systems operate given some difficult constraints, such as operating without power.

Digital clocks consist of two main parts. The first part is some component that ticks at regular intervals. The second part is a pair of counters. One counter increments as ticks occur. The other increments as seconds occur. Determining "now" within digital clocks means comparing the number of seconds against some predetermined starting point. The starting point is known as the *epoch*.

Embedded hardware aside, when your computer is turned off, a small battery-powered clock continues to run. Its electric charge causes a quartz crystal to oscillate rapidly. The clock measures those oscillations and updates its internal counters. In a running computer, the CPU clock frequency becomes the source of regular ticks. A CPU core operates at a fixed frequency. Inside the hardware, a counter can be accessed via CPU instructions and/or by accessing predefined CPU registers. 2

Relying on a CPU's clock can actually cause problems in niche scientific and other high-accuracy domains, such as profiling an application's behavior. When computers use multiple CPUs, which is especially common in high performance computing, each CPU has a slightly different clock rate. Moreover, CPUs perform out-of-order execution. This means that it's impossible for someone creating a benchmarking/profiling software suite to know how long a function takes between two timestamps. The CPU instructions requesting the current timestamp may have shifted.

9.3 Definitions

Unfortunately, this chapter needs to introduce some jargon:

- *Absolute time*—Describes the time that you would tell someone if they were to ask for the time. Also referred to as *wall clock time* and *calendar time*.
- *Real-time clock*—A physical clock that's embedded in the computer's motherboard, which keeps time when the power is off. It's also known as the *CMOS clock*.
- *System clock*—The operating system's view of the time. Upon boot, the OS takes over timekeeping duties from the real-time clock.

All applications derive their idea of time from the system time. The system clock experiences jumps, as it can be manually set to a different position. This jumpiness can confuse some applications.

Monotonically increasing—A clock that never provides the same time twice. This is
a useful property for a computer application because, among other advantages,

¹ Dynamic adjustments to a CPU's clock speed do occur in many processors to conserve power, but these happen infrequently enough from the point of view of the clock as to be insignificant.

² For example, Intel-based processors support the RDTSC instruction, which stands for *Read Time Stamp Counter*.

log messages will never have a repeated timestamp. Unfortunately, preventing time adjustments means being permanently bound to the local clock's skew. Note that the *system clock* is not monotonically increasing.

- Steady clock—This clock provides two guarantees: its seconds are all equal length and it is monotonically increasing. Values from steady clocks are unlikely to align with the system clock's time or absolute time. These typically start at 0 when computers boot up, then count upwards as an internal counter progresses. Although potentially useless for knowing the absolute time, these are handy for calculating the duration between two points in time.
- High accuracy—A clock is highly accurate if the length of its seconds are regular. The difference between two clocks is known as shew. Highly accurate clocks have little skew against the atomic clocks that are humanity's best engineering effort at keeping accurate time.
- *High resolution*—Provides accuracy down to 10 nanoseconds or below. High resolution clocks are typically implemented within CPU chips because there are few devices that can maintain time at such high frequency. CPUs are able to do this. Their units of work are measured in cycles, and cycles have the same duration. A 1 GHz CPU core takes 1 nanosecond to compute one cycle.
- Fast clock—A clock that takes little time to read the time. Fast clocks sacrifice accuracy and precision for speed, however.

9.4 Encoding time

There are many ways to represent time within a computer. The typical approach is to use a pair of 32-bit integers. The first counts the number of seconds that have elapsed. The second represents a fraction of a second. The precision of the fractional part depends on the device in question.

The starting point is arbitrary. The most common epoch in UNIX-based systems is 1 Jan 1970 UTC. Alternatives include 1 Jan 1900 (which happens to be used by NTP), 1 Jan 2000 for more recent applications, and 1 Jan 1601 (which is the beginning of the Gregorian calendar). Using fixed-width integers presents two key advantages and two main challenges:

- Advantages include
 - Simplicity—It's easy to understand the format.
 - Efficiency—Integer arithmetic is the CPU's favorite activity.
- Disadvantages include
 - Fixed-range—All fixed-integer types are finite, implying that time eventually wraps around to 0 again.
 - Imprecise—Integers are discrete, while time is continuous. Different systems
 make different trade-offs relating to subsecond accuracy, leading to rounding errors.

It's also important to note that the general approach is inconsistently implemented. Here are some things seen in the wild to represent the seconds component:

- UNIX timestamps, a 32-bit integer, represents milliseconds since epoch (e.g., 1 Jan 1970).
- MS Windows FILETIME structures (since Windows 2000), a 64-bit unsigned integer, represents 100 nanosecond increments since 1 Jan 1601 (UTC).
- Rust community's chronos crate, a 32-bit signed integer, implements NaiveTime alongside an enum to represent time zones where appropriate.³
- time_t (meaning time type but also called simple time or calendar time) within the C standard library (libc) varies:
 - Dinkumware's libc provides an unsigned long int (e.g., a 32-bit unsigned integer).
 - GNU's libc includes a long int (e.g., a 32-bit signed integer).
 - AVR's libc uses a 32-bit unsigned integer, and its epoch begins at midnight,
 1 January 2000 (UTC).

Fractional parts tend to use the same type as their whole-second counterparts, but this isn't guaranteed. Now, let's take a peek a time zones.

9.4.1 Representing time zones

Time zones are political divisions, rather than technical ones. A soft consensus appears to have been formed around storing another integer that represents the number of seconds offset from UTC.

9.5 clock v0.1.0: Teaching an application how to tell the time

To begin coding our NTP client, let's start by learning how to read time. Figure 9.1 provides a quick overview of how an application does that.

Figure 9.1 An application gets time information from the OS, usually functionally provided by the system's libc implementation.

³ chronos has relatively few quirks, but one of which is sneaking leap seconds into the nanoseconds field.

Listing 9.2, which reads the system time in the local time zone, might almost feel too small to be a full-fledged example. But running the code results in the current time-stamp formatted according to the ISO 8601 standard. The following listing provides its configuration. You'll find the source for this listing in ch9/ch9-clock0/Cargo.toml.

Listing 9.1 Crate configuration for listing 9.2

```
[package]
name = "clock"
version = "0.1.0"
authors = ["Tim McNamara <author@rustinaction.com>"]
edition = "2018"

[dependencies]
chrono = "0.4"
```

The following listing reads and prints the system time. You'll find the source code for the listing in ch9/ch9-clock0/src/main.rs.

Listing 9.2 Reading the system time and printing it on the screen

```
1 use chrono::Local;
2
3 fn main() {
4    let now = Local::now();
5    println!("{}", now);
6 }
Asks for the time in the system's local time zone
```

In listing 9.2, there is a lot of complexity hidden by these eight lines of code. Much of it will be peeled away during the course of the chapter. For now, it's enough to know that chrono::Local provides the magic. It returns a typed value, containing a time zone.

NOTE Interacting with timestamps that don't include time zones or performing other forms of illegal time arithmetic results in the program refusing to compile.

9.6 clock v0.1.1: Formatting timestamps to comply with ISO 8601 and email standards

The application that we'll create is called clock, which reports the current time. You'll find the full application in listing 9.7. Throughout the chapter, the application will be incrementally enhanced to support setting the time manually and via NTP. For the moment, however, the following code shows the result of compiling and running the code from listing 9.8 and sending it the --use-standard timestamp flag.

```
$ cd ch9/ch9-clock1
$ cargo run -- --use-standard rfc2822
warning: associated function is never used: `set`
    --> src/main.rs:12:8
```

9.6.1 Refactoring the clock v0.1.0 code to support a wider architecture

It makes sense to spend a short period of time creating a scaffold for the larger application that clock will become. Within the application, we'll first make a small cosmetic change. Rather than using functions to read the time and adjust it, we'll use static methods of a Clock struct. The following listing, an excerpt from listing 9.7, shows the change from listing 9.2.

Listing 9.3 Reading the time from the local system clock

```
2 use chrono::{DateTime};
 3 use chrono::{Local};
 5 struct Clock;
                                                DateTime < Local > is a
                                                DateTime with the Local
 7 impl Clock {
                                                time zone information.
     fn get() -> DateTime<Local> {
 9
          Local::now()
10
11
12
      fn set() -> ! {
13
       unimplemented!()
       }
14
15 }
```

What on earth is the return type of set ()? The exclamation mark (!) indicates to the compiler that the function never returns (a return value is impossible). It's referred to as the Never type. If the unimplemented!() macro (or its shorter cousin todo!()) is reached at runtime, then the program panics.

Clock is purely acting as a namespace at this stage. Adding a struct now provides some extensibility later on. As the application grows, it might become useful for Clock to contain some state between calls or implement some trait to support new functionality.

NOTE A struct with no fields is known as a *zero-sized type* or ZST. It does not occupy any memory in the resulting application and is purely a compile-time construct.

9.6.2 Formatting the time

This section looks at formatting the time as a UNIX timestamp or a formatted string according to ISO 8601, RFC 2822, and RFC 3339 conventions. The following listing, an excerpt from listing 9.7, demonstrates how to produce timestamps using the functionality provided by chrono. The timestamps are then sent to stdout.

Listing 9.4 Showing the methods used to format timestamps

```
48    let now = Clock::get();
49    match std {
50         "timestamp" => println!("{}", now.timestamp()),
51         "rfc2822" => println!("{}", now.to_rfc2822()),
52         "rfc3339" => println!("{}", now.to_rfc3339()),
53         _ => unreachable!(),
54    }
```

Our clock application (thanks to chrono) supports three time formats—timestamp, rfc2822, and rfc3339:

- *timestamp*—Formats the number of seconds since the epoch, also known as a *UNIX timestamp*.
- rfc2822—Corresponds to RPC 2822 (https://tools.ietf.org/html/rfc2822), which is how time is formatted within email message headers.
- rfc3339—Corresponds to RFC 3339 (https://tools.ietf.org/html/rfc3339). RFC 3339 formats time in a way that is more commonly associated with the ISO 8601 standard. However, ISO 8601 is a slightly stricter standard. Every RFC 3339-compliant timestamp is an ISO 8601-compliant timestamp, but the inverse is not true.

9.6.3 Providing a full command-line interface

Command-line arguments are part of the environment provided to an application from its OS when it's established. These are raw strings. Rust provides some support for accessing the raw Vec<String> via std::env::args, but it can be tedious to develop lots of parsing logic for moderately-sized applications.

Our code wants to be able to validate certain input, such that the desired output format is one that the clock app actually supports. But validating input tends to be irritatingly complex. To avoid this frustration, clock makes use of the clap crate.

There are two main types that are useful for getting started: clap::App and clap::Arg. Each clap::Arg represents a command-line argument and the options that it can represent. clap::App collects these into a single application. To support the public API in table 9.1, the code in listing 9.5 uses three Arg structs that are wrapped together within a single App.

Listing 9.5 is an excerpt from listing 9.7. It demonstrates how to implement the API presented in table 9.1 using clap.

Table 9.1 Usage examples for executing the clock application from the command line. Each command needs to be supported by our parser.

Use	Description	Example output
clock	Default usage. Prints the current time.	2018-06-17T11:25:19
clock get	Provides a get action explicitly with default formatting.	2018-06-17T11:25:19
clock getuse- standard timestamp	Provides a get action and a formatting standard.	1529191458
clock get -s timestamp	Provides a get action and a for- matting standard using shorter notation.	1529191458
clock set <datetime></datetime>	Provides a set action explicitly with default parsing rules.	
<pre>clock setuse- standard timestamp <datetime></datetime></pre>	Provides a set action explicitly and indicates that the input will be a UNIX timestamp.	

Listing 9.5 Using clap to parse command-line arguments

```
let app = App::new("clock")
18
19
       .version("0.1")
20
       .about("Gets and (aspirationally) sets the time.")
21
       .arg(
         Arg::with name("action")
22
23
           .takes value(true)
           .possible_values(&["get", "set"])
24
25
            .default value("get"),
26
       )
27
       .arg(
       Arg::with name("std")
2.8
29
           .short("s")
30
           .long("standard")
           .takes value(true)
31
32
           .possible_values(&[
33
              "rfc2822",
              "rfc3339",
34
35
              "timestamp",
                                                                   The backslash asks
36
           ])
                                                                   Rust to escape the
37
            .default value("rfc3339"),
                                                                   newline and the
38
                                                                   following
39
       .arg(Arg::with_name("datetime").help(
                                                                  indentation.
         "When <action> is 'set', apply <datetime>. \
40
          Otherwise, ignore.",
41
42
       ));
43
44
     let args = app.get matches();
```

clap automatically generates some usage documentation for our clock application on your behalf. Using the --help option triggers its output.

9.6.4 clock v0.1.1: Full project

The following terminal session demonstrates the process of downloading and compiling the clock v0.1.1 project from the public Git repository. It also includes a fragment for accessing the --help option that is mentioned in the previous section:

```
$ git clone https://github.com/rust-in-action/code rust-in-action
$ cd rust-in-action/ch9/ch9-clock1
$ cargo build
  Compiling clock v0.1.1 (rust-in-action/ch9/ch9-clock1)
warning: associated function is never used: `set` <─
                                                       This warning is
 --> src/main.rs:12:6
                                                       eliminated in
                                                      clock v0.1.2.
12 | fn set() -> ! {
  = note: `#[warn(dead code)]` on by default
warning: 1 warning emitted
                         of -- are sent to the resulting executable.
$ cargo run -- --help
. . .
clock 0.1
Gets and sets (aspirationally) the time.
USAGE:
   clock.exe [OPTIONS] [ARGS]
FLAGS:
   -h, --help Prints help information
   -V, --version Prints version information
OPTIONS:
   -s, --use-standard <std> [default: rfc3339]
                              [possible values: rfc2822,
                              rfc3339, timestamp]
ARGS:
   <action> [default: get] [possible values: get, set]
   <datetime> When <action> is 'set', apply <datetime>.
               Otherwise, ignore.
                                       Executes the
$ target/debug/clock
```

Creating the project step by step takes slightly more work. As clock v0.1.1 is a project managed by cargo, it follows the standard structure:

```
clock

— Cargo.toml
— src
— main.rs

See listing 9.6.

See listing 9.7.
```

To create it manually, follow these steps:

1 From the command-line, execute these commands:

```
$ cargo new clock
$ cd clock
$ cargo install cargo-edit
$ cargo add clap@2
$ cargo add chrono@0.4
```

- 2 Compare the contents of your project's Cargo.toml file with listing 9.6. With the exception of the authors field, these should match.
- 3 Replace the contents of src/main.rs with listing 9.7.

The next listing is the project's Cargo.toml file. You'll find it at ch9/ch9-clock1/Cargo.toml. Following that is the project's src/main.rs file, listing 9.7. Its source is in ch9/ch9-clock1/src/main.rs.

Listing 9.6 Crate configuration for clock v0.1.1

```
[package]
name = "clock"
version = "0.1.1"
authors = ["Tim McNamara <author@rustinaction.com>"]
edition = "2018"

[dependencies]
chrono = "0.4"
clap = "2"
```

Listing 9.7 Producing formatted dates from the command line, clock v0.1.1

```
1 use chrono::DateTime;
 2 use chrono::Local;
 3 use clap::{App, Arg};
5 struct Clock;
7 impl Clock {
   fn get() -> DateTime<Local> {
    Local::now()
9
10
11
12
   fn set() -> ! {
13
   unimplemented!()
14
15 }
```

```
16
17 fn main() {
   let app = App::new("clock")
19
       .version("0.1")
20
       .about("Gets and (aspirationally) sets the time.")
21
       .arq(
        Arg::with name("action")
22
23
           .takes value(true)
24
            .possible values(&["get", "set"])
            .default value("get"),
25
26
       )
27
       .arq(
        Arg::with name("std")
28
29
          .short("s")
30
          .long("use-standard")
31
           .takes value(true)
32
           .possible values(&[
33
             "rfc2822",
             "rfc3339",
34
35
              "timestamp",
36
37
            .default value("rfc3339"),
38
39
       .arg(Arg::with name("datetime").help(
         "When <action> is 'set', apply <datetime>. \
40
41
          Otherwise, ignore.",
42
       ));
43
                                                              Supplies a default value
44
     let args = app.get matches();
                                                              to each argument via
45
                                                              default value("get") and
     let action = args.value of("action").unwrap();
46
                                                              default_value("rfc3339").
47
     let std = args.value_of("std").unwrap();
                                                              It's safe to call unwrap()
48
                                                              on these two lines.
49
     if action == "set" {
50
       unimplemented!()
                                   Aborts early as
51
                                   we're not ready to
52
                                   set the time yet
53
    let now = Clock::get();
54
   match std {
       "timestamp" => println!("{}", now.timestamp()),
55
       "rfc2822" => println!("{}", now.to rfc2822()),
57
       "rfc3339" => println!("{}", now.to_rfc3339()),
       _ => unreachable!(),
58
59
60 }
```

9.7 clock v0.1.2: Setting the time

Setting the time is complicated because each OS has its own mechanism for doing so. This requires that we use OS-specific conditional compilation to create a cross-portable tool.

9.7.1 Common behavior

Listing 9.11 provides two implementations of setting the time. These both follow a common pattern:

- Parsing a command-line argument to create a DateTime<FixedOffset> value. The FixedOffset time zone is provided by chrono as a proxy for "whichever time zone is provided by the user." chrono doesn't know at compile time which time zone will be selected.
- 2 Converting the DateTime<FixedOffset> to a DateTime<Local> to enable time zone comparisons.
- 3 Instantiating an OS-specific struct that's used as an argument for the necessary system call (*system calls* are function calls provided by the OS).
- 4 Setting the system's time within an unsafe block. This block is required because responsibility is delegated to the OS.
- 5 Printing the updated time.

WARNING This code uses functions to teleport the system's clock to a different time. This jumpiness can cause system instability.

Some applications expect monotonically increasing time. A smarter (but more complex) approach is to adjust the length of a second for n seconds until the desired time is reached. Functionality is implemented within the Clock struct that was introduced in section 9.6.1.

9.7.2 Setting the time for operating systems that use libc

POSIX-compliant operating systems can have their time set via a call to settimeof-day(), which is provided by libc. libc is the C Standard Library and has lots of historic connections with UNIX operating systems. The C language, in fact, was developed to write UNIX. Even today, interacting with a UNIX derivative involves using the tools provided by the C language. There are two mental hurdles required for Rust programmers to understanding the code in listing 9.11, which we'll address in the following sections:

- The arcane types provided by libc
- The unfamiliarity of providing arguments as pointers

LIBC TYPE NAMING CONVENTIONS

libc uses conventions for naming types that differ from Rust's. libc does not use Pascal-Case to denote a type, preferring to use lowercase. That is, where Rust would use TimeVal, libc uses timeval. The convention changes slightly when dealing with type aliases. Within libc, type aliases append an underscore followed by the letter t (_t) to the type's name. The next two snippets show some libc imports and the equivalent Rust code for building those types.

On line 64 of listing 9.8, you will encounter this line:

```
libc::{timeval, time t, suseconds t};
```

It represents two type aliases and a struct definition. In Rust syntax, these are defined like this:

```
#![allow(non_camel_case_types)]
type time_t = i64;
type suseconds_t = i64;
pub struct timeval {
    pub tv_sec: time_t,
    pub tv_usec: suseconds_t,
}
```

time_t represents the seconds that have elapsed since the epoch. suseconds_t represents the fractional component of the current second.

The types and functions relating to timekeeping involve a lot of indirection. The code is intended to be easy to implement, which means providing local implementors (hardware designers) the opportunity to change aspects as their platforms require. The way this is done is to use type aliases everywhere, rather than sticking to a defined integer type.

Non-Windows Clock Code

The libc library provides a handy function, settimeofday, which we'll use in listing 9.8. The project's Cargo.toml file requires two extra lines to bring libc bindings into the crate for non-Windows platforms:

```
[target.'cfg(not(windows))'.dependencies]
libc = "0.2"

You can add these two lines
to the end of the file.
```

The following listing, an extract from listing 9.11, shows how to set the time with C's standard library, libc. In the listing, we use Linux and BSD operating systems or other similar ones.

Listing 9.8 Setting the time in a libc environment

```
62 #[cfg(not(windows))]
             -> 63 fn set<Tz: TimeZone>(t: DateTime<Tz>) -> () {
               64 use libc::{timeval, time t, suseconds t};
                                                                       The timezone parameter of
                                                                       settimeofday() appears to
               65 use libc::{settimeofday, timezone }
                                                                       be some sort of historic
               66
t is sourced
                                                                       accident. Non-null values
               67
                   let t = t.with_timezone(&Local);
   from the
                                                                       generate an error.
               68 let mut u: timeval = unsafe { zeroed() };
  command
               69
   line and
               70  u.tv_sec = t.timestamp() as time_t;
has already
               71 u.tv_usec =
been parsed.
               72 t.timestamp_subsec_micros() as suseconds_t;
               73
               74 unsafe {
             ⊳ 75
                     let mock tz: *const timezone = std::ptr::null();
               76
                      settimeofday(&u as *const timeval, mock_tz);
               77
                    }
               78 }
```

Makes OS-specific imports within the function to avoid polluting the global scope. libc::settimeofday is a function that modifies the system clock, and suseconds_t, time t, timeval, and timezone are all types used to interact with it.

This code cheekily, and probably perilously, avoids checking whether the settimeofday function is successful. It's quite possible that it isn't. That will be remedied in the next iteration of the clock application.

9.7.3 Setting the time on MS Windows

The code for MS Windows is similar to its libc peers. It is somewhat wordier, as the struct that sets the time has more fields than the second and subsecond part. The rough equivalent of the libc library is called kernel32.dll, which is accessible after including the winapi crate.

WINDOWS API INTEGER TYPES

Windows provides its own take on what to call integral types. This code only makes use of the WORD type, but it can be useful to remember the two other common types that have emerged since computers have used 16-bit CPUs. The following table shows how integer types from kernel32.dll correspond to Rust types.

Windows type	Rust type	Remarks
WORD	u16	Refers to the width of a CPU "word" as it was when Windows was initially created
DWORD	u32	Double word
QWORD	u64	Quadruple word
LARGE_INTEGER	i64	A type defined as a crutch to enable 32-bit and 64-bit platforms to share code
ULARGE_INTEGER	u64	An unsigned version of LARGE_INTEGER

REPRESENTING TIME IN WINDOWS

Windows provides multiple time types. Within our clock application, however, we're mostly interested in SYSTEMTIME. Another type that is provided is FILETIME. The following table describes these types to avoid confusion.

Windows type	Rust type	Remarks
SYSTEMTIME	winapi::SYSTEMTIME	Contains fields for the year, month, day of the week, day of the month, hour, minute, second, and millisecond.
FILETIME	winapi::FILETIME	Analogous to libc::timeval. Contains second and millisecond fields. Microsoft's documentation warns that on 64-bit platforms, its use can cause irritating overflow bugs without finicky type casting, which is why it's not employed here.

WINDOWS CLOCK CODE

As the SYSTEMTIME struct contains many fields, generating one takes a little bit longer. The following listing shows this construct.

Listing 9.9 Setting the time using the Windows kernel32.dll API

```
19
     #[cfg(windows)]
20
     fn set<Tz: TimeZone>(t: DateTime<Tz>) -> () {
21
       use chrono::Weekday;
       use kernel32::SetSystemTime;
22
23
       use winapi::{SYSTEMTIME, WORD};
24
25
       let t = t.with_timezone(&Local);
26
       let mut systime: SYSTEMTIME = unsafe { zeroed() };
2.7
28
29
       let dow = match t.weekday() {
         Weekday::Mon => 1,
3.0
                                              The chrono::Datelike
31
         Weekday::Tue => 2,
                                              trait provides the
         Weekday::Wed => 3,
32
                                              weekday() method.
         Weekday::Thu => 4,
33
                                              Microsoft's developer
         Weekday::Fri => 5,
34
                                              documentation provides
         Weekday::Sat => 6,
                                              the conversion table.
35
36
         Weekday::Sun => 0,
37
       };
38
       let mut ns = t.nanosecond();
39
                                                           As an implementation detail,
40
       let mut leap = 0;
                                                            chrono represents leap seconds
       let is_leap_second = ns > 1_000_000_000;
41
                                                           by adding an extra second
42
                                                           within the nanoseconds field. To
43
        if is leap second {
                                                           convert the nanoseconds to
                                                           milliseconds as required by
44
         ns -= 1 000 000 000;
                                                           Windows, we need to account
45
          leap += 1;
                                                           for this.
46
47
48
       systime.wYear = t.year() as WORD;
        systime.wMonth = t.month() as WORD;
49
50
        systime.wDayOfWeek = dow as WORD;
       systime.wDay = t.day() as WORD;
51
52
        systime.wHour = t.hour() as WORD;
        systime.wMinute = t.minute() as WORD;
53
54
       systime.wSecond = (leap + t.second()) as WORD;
55
        systime.wMilliseconds = (ns / 1 000 000) as WORD;
56
57
       let systime ptr = &systime as *const SYSTEMTIME;
58
                                              From the perspective of the Rust compiler,
59
       unsafe {
60
          SetSystemTime(systime ptr);
                                              giving something else direct access to memory
                                              is unsafe. Rust cannot guarantee that the
61
                                              Windows kernel will be well-behaved.
62
```

9.7.4 clock v0.1.2: The full code listing

clock v0.1.2 follows the same project structure as v0.1.1, which is repeated here. To create platform-specific behavior, some adjustments are required to Cargo.toml.

```
clock
Cargo.toml
src
main.rs

See listing 9.10.
See listing 9.11.
```

Listings 9.10 and 9.11 provide the full source code for the project. These are available for download from ch9/ch9-clock0/Cargo.toml and ch9/ch9-clock0/src/main.rs, respectively.

Listing 9.10 Crate configuration for listing 9.11

```
[package]
name = "clock"
version = "0.1.2"
authors = ["Tim McNamara <author@rustinaction.com>"]
edition = "2018"

[dependencies]
chrono = "0.4"
clap = "2"

[target.'cfg(windows)'.dependencies]
winapi = "0.2"
kernel32-sys = "0.2"

[target.'cfg(not(windows))'.dependencies]
libc = "0.2"
```

Listing 9.11 Cross-portable code for setting the system time

```
1 #[cfq(windows)]
 2 use kernel32;
 3 #[cfg(not(windows))]
 4 use libc;
 5 #[cfg(windows)]
 6 use winapi;
 8 use chrono::{DateTime, Local, TimeZone};
 9 use clap::{App, Arg};
10 use std::mem::zeroed;
11
12 struct Clock;
13
14 impl Clock {
15 fn get() -> DateTime<Local> {
16
     Local::now()
17
18
```

```
19
    #[cfq(windows)]
20
    fn set<Tz: TimeZone>(t: DateTime<Tz>) -> () {
21
    use chrono::Weekday;
22
     use kernel32::SetSystemTime;
23
      use winapi::{SYSTEMTIME, WORD};
24
      let t = t.with timezone(&Local);
25
26
2.7
      let mut systime: SYSTEMTIME = unsafe { zeroed() };
28
      let dow = match t.weekday() {
29
30
        Weekday::Mon => 1,
        Weekday::Tue => 2,
31
32
        Weekday::Wed => 3,
33
        Weekday::Thu => 4,
        Weekday::Fri => 5,
34
        Weekday::Sat => 6,
35
36
        Weekday::Sun => 0,
37
       };
38

        _ => unreachable!(),
143 }
144 }
```

9.8 Improving error handling

Those readers who have dealt with operating systems before will probably be dismayed at some of the code in section 9.7. Among other things, it doesn't check to see whether the calls to settimeofday() and SetSystemTime() were actually successful.

There are multiple reasons why setting the time might fail. The most obvious one is that the user who is attempting to set the time lacks permission to do so. The robust approach is to have Clock::set(t) return Result. As that requires modifying two functions that we have already spent some time explaining in depth, let's introduce a workaround that instead makes use of the operating system's error reporting:

```
fn main() {
  // ...
  if action == "set" {
    // ...
                                                      Deconstructs maybe error, a Rust
                                                      type, to convert it into a raw i32
    Clock::set(t);
                                                      value that's easy to match
    let maybe error =
      std::io::Error::last os error();
    let os error code =
                                                        Matching on a raw integer saves
      &maybe error.raw os error();
                                                        importing an enum, but sacrifices
                                                        type safety. Production-ready code
    match os error code {
                                                        shouldn't cheat in this way.
      Some(0) => (),
      Some() => eprintln!("Unable to set the time: {:?}", maybe error),
      None \Rightarrow (),
}
```

After calls to Clock::set(t), Rust happily talks to the OS via std::io::Error::last _os_error(). Rust checks to see if an error code has been generated.

9.9 clock v0.1.3: Resolving differences between clocks with the Network Time Protocol (NTP)

Coming to a consensus about the correct time is known formally as *clock synchroniza*tion. There are multiple international standards for synchronizing clocks. This section focuses on the most prominent one—the Network Time Protocol (NTP).

NTP has existed since the mid-1980s, and it has proven to be very stable. Its on-wire format has not changed in the first four revisions of the protocol, with backwards compatibility retained the entire time. NTP operates in two modes that can loosely be described as *always on* and *request/response*.

The always on mode allows multiple computers to work in a peer-to-peer fashion to converge on an agreed definition of *now*. It requires a software daemon or service to run constantly on each device, but it can achieve tight synchronization within local networks.

The request/response mode is much simpler. Local clients request the time via a single message and then parse the response, keeping track of the elapsed time. The client can then compare the original timestamp with the timestamp sent from the server, alter any delays caused by network latency, and make any necessary adjustments to move the local clock towards the server's time.

Which server should your computer connect to? NTP works by establishing a hierarchy. At the center is a small network of atomic clocks. There are also national pools of servers.

NTP allows clients to request the time from computers that are closer to atomic clocks. But that only gets us part of the way. Let's say that your computer asks 10 computers what they think the time is. Now we have 10 assertions about the time, and the network lag will differ for each source!

9.9.1 Sending NTP requests and interpreting responses

Let's consider a client-server situation where your computer wants to correct its own time. For every computer that you check with—let's call these *time servers*—there are two messages:

- The message from your computer to each time server is the *request*.
- The reply is known as the *response*.

These two messages generate four time points. Note that these occur in serial:

- T_1 —The client's timestamp for when the request was sent. Referred to as t1 in code.
- T_2 —The time server's timestamp for when the request was received. Referred to as t2 in code.
- The time server's timestamp for when it sends its response. Referred to as t3 in code.
- T_4 —The client's timestamp for when the response was received. Referred to as ± 4 in code.

The names T_1 – T_4 are designated by the RFC 2030 specification. Figure 9.2 shows the timestamps.

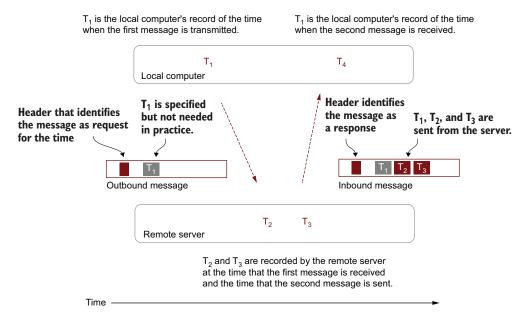

Figure 9.2 Timestamps that are defined within the NTP standard

To see what this means in code, spend a few moments looking through the following listing. Lines 2–12 deal with establishing a connection. Lines 14–21 produce T_1 – T_4 .

Listing 9.12 Defining a function that sends NTP messages

```
1 fn ntp roundtrip(
     host: &str,
 3
     port: u16,
 4 ) -> Result<NTPResult, std::io::Error> {
     let destination = format!("{}:{}", host, port);
 5
 6
     let timeout = Duration::from secs(1);
 7
 8
     let request = NTPMessage::client();
 9
     let mut response = NTPMessage::new();
10
11
     let message = request.data;
12
13
     let udp = UdpSocket::bind(LOCAL ADDR)?;
14
     udp.connect(&destination).expect("unable to connect");
15
                                            This code cheats slightly by not encoding tl in the
16
     let t1 = Utc::now();
                                            outbound message. In practice, however, this works
17
                                            perfectly well and requires fractionally less work.
```

```
udp.send(&message)?;
18
                                                      Sends a request payload (defined
19
     udp.set read timeout(Some(timeout))?;
                                                      elsewhere) to the server
20
     udp.recv from(&mut response.data)?; <=</pre>
21
                                                    Blocks the application until
    let t4 = Utc::now();
                                                    data is ready to be received
22
23
    let t2: DateTime<Utc> =
24
                                      rx time() stands for received
      response
25
                                      timestamp and is the time
26
       .rx_time()
                                      that the server received the
        .unwrap()
27
                                      client's message.
28
        .into();
29
    let t3: DateTime<Utc> =
30
                                      tx time() stands for
      response
31
                                      transmitted timestamp
        .tx time()
                                      and is the time that the
33
        .unwrap()
                                      server sent the reply.
34
         .into();
35
    Ok(NTPResult {
36
37
      t1: t1,
38
       t2: t2,
      t3: t3,
40
      t4: t4,
41 })
42 }
```

 T_1 – T_4 , encapsulated in listing 9.12 as NTPResult, are all that's required to judge whether the local time matches the server's time. The protocol contains more related to error handling, but that's avoided here for simplicity. Otherwise, it's a perfectly capable NTP client.

9.9.2 Adjusting the local time as a result of the server's response

Given that our client has received at least one (and hopefully a few more) NTP responses, all that's left to do is to calculate the "right" time. But wait, which time is right? All we have are relative timestamps. There is still no universal "truth" that we've been given access to.

NOTE For those readers who don't enjoy Greek letters, feel free to skim or even skip the next few paragraphs.

The NTP documentation provides two equations to help resolve the situation. Our aim is to calculate two values. Table 9.2 shows the calculations.

- The time offset is what we're ultimately interested in. It is denoted as θ (theta) by the official documentation. When θ is a positive number, our clock is fast. When it is negative, our clock is slow.
- The delay caused by network congestion, latency, and other noise. This is denoted as δ (delta). A large δ implies that the reading is less reliable. Our code uses this value to follow servers that respond quickly.

Table 9.2 How to calculate δ and θ in NTP

```
\delta = (\mathsf{T}_4 - \mathsf{T}_1) - (\mathsf{T}_3 - \mathsf{T}_2) (\mathsf{T}_4 - \mathsf{T}_1) \text{ calculates the total time spent on the client's side. } (\mathsf{T}_3 - \mathsf{T}_2) calculates the total time spent on the server's side. The distinction between the two differences (e.g., \delta), is an estimate of the difference between the clocks, plus a delay caused by network traffic and processing. \theta = (\ (\mathsf{T}_2 - \mathsf{T}_1) + (\mathsf{T}_4 - \mathsf{T}_3)\ )\ /\ 2 We take the average of the two pairs of timestamps.
```

The mathematics can be confusing because there is always an innate desire to know what the time *actually is*. That's impossible to know. All we have are assertions.

NTP is designed to operate multiple times per day, with participants nudging their clocks incrementally over time. Given sufficient adjustments, θ tends to 0 while δ remains relatively stable.

The standard is quite prescriptive about the formula to carry out the adjustments. For example, the reference implementation of NTP includes some useful filtering to limit the effect of bad actors and other spurious results. But we're going to cheat. We'll just take a mean of the differences, weighted by $1/\theta^2$. This aggressively penalizes slow servers. To minimize the likelihood of any negative outcomes:

- We'll check the time with known "good" actors. In particular, we'll use time servers
 hosted by major OS vendors and other reliable sources to minimize the chances
 of someone sending us a questionable result.
- *No single result will affect the result too much.* We'll provide a cap of 200 ms on any adjustments we make to the local time.

The following listing, an extract from listing 9.15, shows this process for multiple time servers.

Listing 9.13 Adjusting the time according to the responses

```
175 fn check time() -> Result<f64, std::io::Error> {
      const NTP PORT: u16 = 123;
177
178
      let servers = [
                                        Google's time servers implement leap seconds
        "time.nist.gov",
179
                                        by expanding the length of a second rather than
180
        "time.apple.com",
                                        adding an extra second. Thus, for one day
       "time.euro.apple.com",
181
                                       approximately every 18 months, this server
       "time.google.com",
182
                                     reports a different time than the others.
183
       "time2.google.com",
       //"time.windows.com",
                                           At the time of writing, Microsoft's time server
185
      ];
                                           provides a time that's 15 s ahead of its peers.
186
187
      let mut times = Vec::with capacity(servers.len());
188
189
     for &server in servers.iter() {
190
        print!("{} =>", server);
191
192
       let calc = ntp roundtrip(&server, NTP PORT);
```

```
193
      match calc {
194
       Ok(time) => {
          println!(" {}ms away from local system time", time.offset());
197
           times.push(time);
198
          Err( ) => {
199
200
            println!(" ? [response took too long]")
201
202
        };
203
204
      let mut offsets = Vec::with capacity(servers.len());
205
206
      let mut offset weights = Vec::with capacity(servers.len());
207
208
    for time in &times {
209
      let offset = time.offset() as f64;
210
       let delay = time.delay() as f64;
211
       let weight = 1_000_000.0 / (delay * delay);
212
                                                              Penalizes slow servers
213
       if weight.is finite() {
                                                              by substantially
         offsets.push(offset);
214
                                                              decreasing their
215
          offset weights.push(weight);
                                                              relative weights
216
217
218
219
      let avq offset = weighted mean(&offsets, &offset weights);
220
221
      Ok(avg offset)
222 }
```

9.9.3 Converting between time representations that use different precisions and epochs

chrono represents the fractional part of a second, down to a nanosecond precision, whereas NTP can represent times that differ by approximately 250 picoseconds. That's roughly four times more precise! The different internal representations used imply that some accuracy is likely to be lost during conversions.

The From trait is the mechanism for telling Rust that two types can be converted. From provides the from() method, which is encountered early on in one's Rust career (in examples such as String::from("Hello, world!")).

The next listing, a combination of three extracts from listing 9.15, provides implementations of the $\mathtt{std}:\mathtt{convert}:\mathtt{From}$ trait. This code enables the .into() calls on lines 28 and 34 of listing 9.13.

Listing 9.14 Converting between chrono::DateTime and NTP timestamps

```
19 const NTP_TO_UNIX_SECONDS: i64 = 2_208_988_800;  

Number of seconds between 1 Jan 1900 (the NTP epoch) and 1 Jan 1970 (the UNIX epoch)
```

```
22 #[derive(Default, Debug, Copy, Clone)]
23 struct NTPTimestamp {
                                 Our internal type
24 seconds: u32,
                                 represents an NTP
   fraction: u32,
                                 timestamp.
26 }
52 impl From<NTPTimestamp> for DateTime<Utc> {
   fn from(ntp: NTPTimestamp) -> Self {
      let secs = ntp.seconds as i64 - NTP TO UNIX SECONDS;
55
      let mut nanos = ntp.fraction as f64;
     nanos *= 1e9;
56
57
     nanos /= 2 f64.powi(32);
58
59
     Utc.timestamp(secs, nanos as u32)
                                                             You can implement
60
                                                             these conversions
61 }
                                                             using bit-shift
                                                             operations, but at
62
                                                             the expense of even
63 impl From<DateTime<Utc>> for NTPTimestamp {
                                                             less readability.
   fn from(utc: DateTime<Utc>) -> Self {
65
      let secs = utc.timestamp() + NTP TO UNIX SECONDS;
66
      let mut fraction = utc.nanosecond() as f64;
     fraction *= 2 f64.powi(32);
67
     fraction /= 1e9;
68
69
70 NTPTimestamp {
      seconds: secs as u32,
72
        fraction: fraction as u32,
     }
73
74
     }
75 }
```

From has a reciprocal peer, Into. Implementing From allows Rust to automatically generate an Into implementation on its own, except in advanced cases. In those cases, it's likely that developers already possess the knowledge required to implement Into manually and so probably don't need assistance here.

9.9.4 clock v0.1.3: The full code listing

The complete code listing for our clock application is presented in listing 9.15. Taken in its full glory, the whole of the clock application can look quite large and imposing. Hopefully, there is no new Rust syntax to digest within the listing. The source for this listing is in ch9/ch9-clock3/src/main.rs.

Summary

- Keeping track of elapsed time is difficult. Digital clocks ultimately rely on fuzzy signals from analog systems.
- Representing time is difficult. Libraries and standards disagree about how much precision is required and when to start.
- Establishing truth in a distributed system is difficult. Although we continually deceive ourselves otherwise, there is no single arbiter of what time it is. The best we can hope for is that all of the computers in our network are reasonably close to each other.
- A struct with no fields is known as a zero-sized type or ZST. It does not occupy any memory in the resulting application and is purely a compile-time construct.
- Creating cross-portable applications is possible with Rust. Adding platformspecific implementations of functions requires the precise use of the cfg annotation, but it can be done.
- When interfacing with external libraries, such as the API provided by the operating system (OS), a type conversion step is almost always required. Rust's type system does not extend to libraries that it did not create!

Summary 327

 System calls are used to make function calls to the OS. This invokes a complex interaction between the OS, the CPU, and the application.

- The Windows API typically uses verbose PascalCase identifiers, whereas operating systems from the POSIX tradition typically use terse lowercase identifiers.
- Be precise when making assumptions about the meaning of terms such as epoch and time zone. There is often hidden context lurking beneath the surface.
- Time can go backwards. Never write an application that relies on monotonically increasing time without ensuring that it requests a monotonically increasing clock from the OS.

Processes, threads, and containers

This chapter covers

- Concurrent programming in Rust
- How to distinguish processes, threads, and containers
- Channels and message passing
- Task queues

So far this book has almost completely avoided two fundamental terms of systems programming: threads and processes. Instead, the book has used the single term: program. This chapter expands our vocabulary.

Processes, threads, and containers are abstractions created to enable multiple tasks to be carried out at the same time. This enables *concurrency*. Its peer term, *parallelism*, means to make use of multiple physical CPU cores at the same time.

Counterintuitively, it is possible to have a concurrent system on a single CPU core. Because accessing data from memory and I/O take a long time, threads requesting data can be set to a *blocked* state. Blocked threads are rescheduled when their data is available.

Concurrency, or doing multiple things at the same time, is difficult to introduce into a computer program. Employing concurrency effectively involves both new concepts and new syntax.

The aim of this chapter is to give you the confidence to explore more advanced material. You will have a solid understanding of the different tools that are available to you as an applications programmer. This chapter exposes you to the standard library and the well engineered crates crossbeam and rayon. It will enable you to use them, though it won't give you sufficient background to be able to implement your own concurrency crates. The chapter follows the following structure:

- It introduces you to Rust's closure syntax in section 10.1. Closures are also known as anonymous functions and lambda functions. The syntax is important because the standard library and many (perhaps all) external crates rely on that syntax to provide support for Rust's concurrency model.
- It provides a quick lesson on spawning threads in section 10.2. You'll learn what a thread is and how to create (spawn) those. You'll also encounter a discussion of why programmers are warned against spawning tens of thousands of threads.
- It distinguishes between functions and closures in section 10.3. Conflating these two concepts can be a source of confusion for programmers new to Rust as these are often indistinguishable in other languages.
- It follows with a large project in section 10.4. You'll implement a multithreaded parser and a code generator using multiple strategies. As a nice aside, you get to create procedural art along the way.
- The chapter concludes with an overview of other forms of concurrency. This includes processes and containers.

10.1 Anonymous functions

This chapter is fairly dense, so let's get some points on the board quickly with some basic syntax and practical examples. We'll circle back to fill in a lot of the conceptual and theoretical material.

Threads and other forms of code that can run concurrently use a form of function definition that we've avoided for the bulk of the book. Taking a look at it now, defining a function looks like this:

```
fn add(a: i32, b: i32) -> i32 {
  a + b
}
```

The (loosely) equivalent lambda function is

```
let add = |a,b| { a + b };
```

Lambda functions are denoted by the pair of vertical bars (|...|) followed by curly brackets $(\{...\})$. The pair of vertical bars lets you define arguments. Lambda functions in Rust can read variables from within their scope. These are *closures*.

Unlike regular functions, lambda functions cannot be defined in global scope. The following listing gets around this by defining one within its main(). It defines two

functions, a regular function and a lambda function, and then checks that these produce the same result.

Listing 10.1 Defining two functions and checking the result

```
fn add(a: i32, b: i32) -> i32 {
   a + b
}
fn main() {
  let lambda_add = |a,b| { a + b };
  assert_eq!(add(4,5), lambda_add(4,5));
}
```

When you run listing 10.1, it executes happily (and silently). Let's now see how to put this functionality to work.

10.2 Spawning threads

Threads are the primary mechanism that operating systems provide for enabling concurrent execution. Modern operating systems ensure that each thread has fair access to the CPU. Understanding how to create threads (often referred to as spawning treads) and understanding their impact are fundamental skills for programmers wanting to make use of multi-core CPUs.

10.2.1 Introduction to closures

To spawn a thread in Rust, we pass an anonymous function to std::thread::spawn(). As described in section 10.1, anonymous functions are defined with two vertical bars to provide arguments and then curly brackets for the function's body. Because spawn() doesn't take any arguments, you will typically encounter this syntax:

When the spawned thread wants to access variables that are defined in the parent's scope, called a *capture*, Rust often complains that captures must be moved into the closure. To indicate that you want to move ownership, anonymous functions take a move keyword:

Why is move required? Closures spawned in subthreads can potentially outlive their calling scope. As Rust will always ensure that accessing the data is valid, it requires

ownership to move to the closure itself. Here are some guidelines for using captures while you gain an understanding of how these work:

- To reduce friction at compile time, implement Copy.
- Values originating in outer scopes may need to have a static lifetime.
- Spawned subthreads can outlive their parents. That implies that ownership should pass to the subthread with move.

10.2.2 Spawning a thread

A simple task waits, sleeping the CPU for 300 ms (milliseconds). If you have a 3 GHz CPU, you're getting it to rest for nearly 1 billion cycles. Those electrons will be very relieved. When executed, listing 10.2 prints the total duration (in "wall clock" time) of both executing threads. Here's the output:

300.218594ms

Listing 10.2 Sleeping a subthread for 300 ms

```
1 use std::{thread, time};
2
3 fn main() {
    let start = time::Instant::now();
6
   let handler = thread::spawn(|| {
7
     let pause = time::Duration::from millis(300);
8
      thread::sleep(pause.clone());
9
    });
10
11
    handler.join().unwrap();
12
13
    let finish = time::Instant::now();
14
    println!("{:02?}", finish.duration since(start));
16 }
```

If you had encountered multi-threaded programming before, you would have been introduced to join on line 11. Using join is fairly common, but what does it mean?

join is an extension of the thread metaphor. When threads are spawned, these are said to have *forked* from their parent thread. To join threads means to weave these back together again.

In practice, *join* means wait for the other thread to finish. The <code>join()</code> function instructs the OS to defer scheduling the calling thread until the other thread finishes.

10.2.3 Effect of spawning a few threads

In ideal settings, adding a second thread doubles the work we can do in the same amount of time. Each thread can gets its work done independently. Reality is not ideal, unfortunately. This has created a myth that threads are slow to create and bulky to maintain. This section aims to dispel that myth. When used as intended, threads perform very well.

Listing 10.3 shows a program that measures the overall time taken for two threads to perform the job that was carried out by a single thread in listing 10.2. If adding threads take a long time, we would expect the duration of listing 10.3's code to be longer.

As you'll notice, there is a negligible impact from creating one or two threads. As with listing 10.2, listing 10.3 prints almost the same output:

The difference in these two runs on my computer was 0.24 ms. While by no means a robust benchmark suite, it does indicate that spawning a thread isn't a tremendous performance hit.

Listing 10.3 Creating two subthreads to perform work on our behalf

```
1 use std::{thread, time};
 3 fn main() {
    let start = time::Instant::now();
 5
    let handler 1 = thread::spawn(move | | {
 7
      let pause = time::Duration::from millis(300);
 8
         thread::sleep(pause.clone());
 9
    });
10
     let handler_2 = thread::spawn(move | | {
11
12
      let pause = time::Duration::from millis(300);
13
         thread::sleep(pause.clone());
14
    });
15
    handler 1.join().unwrap();
16
    handler 2.join().unwrap();
17
18
19
    let finish = time::Instant::now();
20
21
    println!("{:?}", finish.duration_since(start));
22 }
```

If you've had any exposure to the field before, you may have heard that threads "don't scale." What does that mean?

Every thread requires its own memory, and by implication, we'll eventually exhaust our system's memory. Before that terminal point, though, thread creation begins to trigger slowdowns in other areas. As the number of threads to schedule increases, the OS scheduler's work increases. When there are many threads to schedule, deciding which thread to schedule next takes more time.

10.2.4 Effect of spawning many threads

Spawning threads is not free. It demands memory and CPU time. Switching between threads also invalidates caches.

Figure 10.1 shows the data generated by successive runs of listing 10.4. The variance stays quite tight until about 400 threads per batch. After that, there's almost no knowing how long a 20 ms sleep will take.

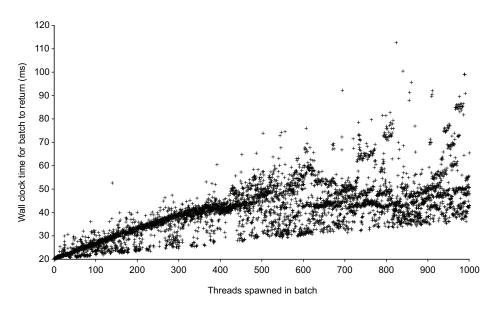

Figure 10.1 Duration needed to wait for threads to sleep 20 ms

And, if you're thinking that sleeping is not a representative workload, figure 10.2 shows the next plot, which is even more telling. It asks each thread to enter a spin loop.

Figure 10.2 provides features that are worth focusing in on briefly. First, for the first seven or so batches, the spin loop version returned closer to 20 ms. The operating system's sleep functionality isn't perfectly accurate, however. If you want to sleep pause a thread for short amounts of time, or if your application is sensitive to timing, use a spin loop.¹

Second, CPU-intensive multithreading doesn't scale well past the number of physical cores. The benchmarking was performed on a 6-core CPU (the Intel i7-8750H) with hyper-threading disabled. Figure 10.3 shows that as soon as the thread count exceeds the core count, performance degrades quickly.

¹ It's also possible to use both: sleep for the bulk of the time and a spin loop towards the end.

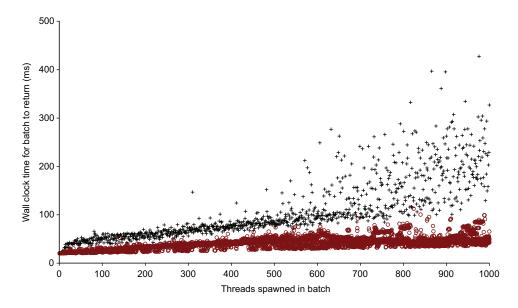

Figure 10.2 Comparing the time taken to wait for 20m using the sleep strategy (circles) versus the spin lock strategy (plus symbols). This chart shows the differences that occur as hundreds of threads compete.

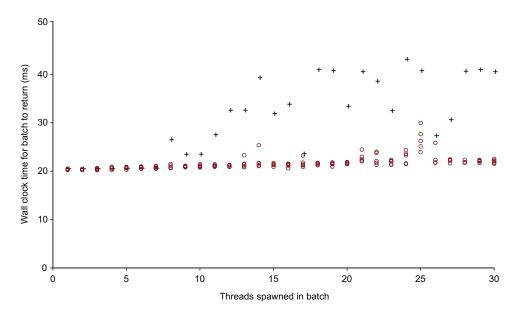

Figure 10.3 Comparing the time taken to wait for 20m using the sleep strategy (circles) versus the spin lock strategy (plus symbols). This chart shows the differences that occur as the number of threads exceeds the number of CPU cores (6).

10.2.5 Reproducing the results

Now that we've seen the effects of threading, let's look at the code that generated the input data to the plots in figures 10.1–10.2. You are welcome to reproduce the results. To do so, write the output of listings 10.4 and 10.5 to two files, and then analyze the resulting data.

Listing 10.4, whose source code is available at c10/ch10-multijoin/src/main.rs, suspends threads for 20 ms with a sleep. A *sleep* is a request to the OS that the thread should be suspended until the time has passed. Listing 10.5, whose source code is available at c10/ch10-busythreads/src/main.rs, uses the *busy wait* strategy (also known as *busy loop* and *spin loop*) to pause for 20 ms.

Listing 10.4 Using thread::sleep to suspend threads for 20 ms

```
1 use std::{thread, time};
 3 fn main() {
4
    for n in 1..1001 {
 5
       let mut handlers: Vec<thread::JoinHandle<()>> = Vec::with capacity(n);
 6
       let start = time::Instant::now();
 7
 8
      for m in 0..n {
        let handle = thread::spawn(|| {
 9
           let pause = time::Duration::from millis(20);
10
11
           thread::sleep(pause);
12
         });
        handlers.push(handle);
13
14
15
        while let Some(handle) = handlers.pop() {
16
17
             handle.join();
18
19
2.0
       let finish = time::Instant::now();
       println!("{}\t{:02?}", n, finish.duration since(start));
21
22
23 }
```

Listing 10.5 Using a spin loop waiting strategy

```
1 use std::{thread, time};
3 fn main() {
    for n in 1..1001 {
5
      let mut handlers: Vec<thread::JoinHandle<()>> = Vec::with_capacity(n);
6
7
      let start = time::Instant::now();
8
     for m in 0..n {
9
        let handle = thread::spawn(|| {
10
          let start = time::Instant::now();
11
          let pause = time::Duration::from_millis(20);
```

```
while start.elapsed() < pause {</pre>
12
13
             thread::yield now();
14
15
         });
16
         handlers.push(handle);
17
18
19
       while let Some(handle) = handlers.pop() {
2.0
         handle.join();
21
22
23
      let finish = time::Instant::now();
       println!("{}\t{:02?}", n, finish.duration since(start));
24
25
26 }
```

The control flow we've chosen for lines 19–21 is slightly odd. Rather than iterating through the handlers vector, we call pop() and then drain it. The following two snippets compare the more familiar for loop (listing 10.6) with the control flow mechanism that is actually employed (listing 10.7).

Listing 10.6 What we would expect to see in listing 10.5

```
19 for handle in &handlers {
20    handle.join();
21 }
```

Listing 10.7 Code that's actually used in listing 10.5

```
19 while let Some(handle) = handlers.pop() {
20    handle.join();
21 }
```

Why use the more complex control flow mechanism? It might help to remember that once we join a thread back to the main thread, it ceases to exist. Rust won't allow us to retain a reference to something that doesn't exist. Therefore, to call join() on a thread handler within handlers, the thread handler must be removed from handlers. That poses a problem. A for loop does not permit modifications to the data being iterated over. Instead, the while loop allows us to repeatedly gain mutable access when calling handlers.pop().

Listing 10.8 provides a broken implementation of the spin loop strategy. It is broken because it uses the more familiar for loop control flow that was avoided in listing 10.5. You'll find the source for this listing in c10/ch10-busythreads-broken/src/main.rs. Its output follows the listing.

Listing 10.8 Using a spin loop waiting strategy

```
1 use std::{thread, time};
```

```
3 fn main() {
 4 for n in 1..1001 {
      let mut handlers: Vec<thread::JoinHandle<()>> = Vec::with capacity(n);
 6
 7
      let start = time::Instant::now();
 8
     for m in 0..n {
       let handle = thread::spawn(|| {
 9
10
          let start = time::Instant::now();
11
          let pause = time::Duration::from millis(20);
12
          while start.elapsed() < pause {</pre>
            thread::yield now();
13
14
         }
       });
15
16
       handlers.push(handle);
17
18
     for handle in &handlers {
19
20
       handle.join();
21
22
23
      let finish = time::Instant::now();
      println!("{}\t{:02?}", n, finish.duration since(start));
24
25
26 }
```

Here is the output generated when attempting to compile listing 10.8:

This error is saying that taking a reference isn't valid here. That's because multiple threads might also be taking their own references to the underlying threads. And those references need to be valid.

Astute readers know that there is actually a simpler way to get around this problem than what was used in listing 10.5. As the following listing shows, simply remove the ampersand.

Listing 10.9 What we could have used in listing 10.5

```
19 for handle in handlers {
20    handle.join();
21 }
```

What we've encountered is one of those rare cases where taking a reference to an object causes more issues than using the object directly. Iterating over handlers directly retains ownership. That pushes any concerns about shared access to the side, and we can proceed as intended.

YIELDING CONTROL WITH THREAD::YIELD_NOW()

As a reminder, the busy loop within listing 10.5 includes some unfamiliar code, repeated in the following listing. This section explains its significance.

Listing 10.10 Showing the current thread-yielding execution

```
14 while start.elapsed() < pause {
15   thread::yield_now();
16 }</pre>
```

std::thread::yield_now() is a signal to the OS that the current thread should be unscheduled. This allows other threads to proceed while the current thread is still waiting for the 20 ms to arrive. A downside to yielding is that we don't know if we'll be able to resume at exactly 20 ms.

An alternative to yielding is to use the function std::sync::atomic::spin_loop_hint().spin_loop_hint() avoids the OS; instead, it directly signals the CPU. A CPU might use that hint to turn off functionality, thus saving power usage.

NOTE The spin_loop_hint() instruction is not present for every CPU. On platforms that don't support it, spin_loop_hint() does nothing.

10.2.6 Shared variables

In our threading benchmarks, we created pause variables in each thread. If you're not sure what I'm referring to, the following listing provides an excerpt from listing 10.5.

Listing 10.11 Emphasizing the needless creation of time::Duration instances

```
9 let handle = thread::spawn(|| {
10    let start = time::Instant::now();
11    let pause = time::Duration::from_millis(20);
12    while start.elapsed() < pause {
13         thread::yield_now();
14    }
15 });</pre>
This variable doesn't need to be created in each thread.
```

We want to be able to write something like the following listing. The source for this listing is ch10/ch10-sharedpause-broken/src/main.rs.

Listing 10.12 Attempting to share a variable in multiple subthreads

```
1 use std::{thread,time};
 3 fn main() {
    let pause = time::Duration::from millis(20);
     let handle1 = thread::spawn(|| {
 5
 6
      thread::sleep(pause);
 7
     });
 8
    let handle2 = thread::spawn(|| {
 9
      thread::sleep(pause);
10
    });
11
12
    handle1.join();
13
     handle2.join();
14 }
If we run listing 10.12, we'll receive a verbose—and surprisingly helpful—error message:
$ cargo run -q
error[E0373]: closure may outlive the current function, but it borrows
'pause', which is owned by the current function
--> src/main.rs:5:33
5 I
        let handle1 = thread::spawn(|| {
                                   ^^ may outlive borrowed value `pause`
            thread::sleep(pause);
6
                          ---- `pause` is borrowed here
note: function requires argument type to outlive `'static`
 --> src/main.rs:5:19
          let handle1 = thread::spawn(|| {
5
6 l
              thread::sleep(pause);
         });
7 | |
help: to force the closure to take ownership of `pause` (and any other
references variables), use the `move` keyword
5
        let handle1 = thread::spawn(move | | {
error[E0373]: closure may outlive the current function, but it borrows
`pause`, which is owned by the current function
 --> src/main.rs:8:33
        let handle2 = thread::spawn(|| {
8
                                    ^^ may outlive borrowed value `pause`
            thread::sleep(pause);
                          ---- `pause` is borrowed here
note: function requires argument type to outlive `'static`
```

--> src/main.rs:8:19

The fix is to add the move keyword to where the closures are created, as hinted at in section 10.2.1. The following listing adds the move keyword, which switches the closures to use move semantics. That, in turn, relies on Copy.

Listing 10.13 Using a variable defined in a parent scope in multiple closures

```
1 use std::{thread,time};
 3 fn main() {
    let pause = time::Duration::from millis(20);
   let handle1 = thread::spawn(move | | {
 6
     thread::sleep(pause);
 7
    let handle2 = thread::spawn(move | | {
 9
     thread::sleep(pause);
10
    });
11
12
   handle1.join();
13
    handle2.join();
14 }
```

The details of why this works are interesting. Be sure to read the following section to learn those.

10.3 Differences between closures and functions

There are some differences between closures (|| {}) and functions (fn). The differences prevent closures and functions from being used interchangeably, which can cause problems for learners.

Closures and functions have different internal representations. Closures are anonymous structs that implement the std::ops::FnOnce trait and potentially std::ops::Fn

and std::ops::FnMut. Those structs are invisible in source code but contain any variables from the closure's environment that are used inside it.

Functions are implemented as function pointers. A *function pointer* is a pointer that points to code, not data. Code, when used in this sense, is computer memory that has been marked as executable. To complicate matters, closures that do not enclose any variables from their environment are also function pointers.

Forcing the compiler to reveal the type of closure

The concrete type of a Rust closure is inaccessible as source code. The compiler creates it. To retrieve it, force a compiler error like this:

```
1 fn main() {
2 let a = 20; be assigned to a variable.
3
4 let add_to_a = |b| { a + b };
5 add_to_a == ();
6 }

Closures are values and can be assigned to a variable.

be assigned to a variable.

add_to_a = |b| { a + b };

contact the compiler quickly reports it as an error message.
```

Among other errors, the compiler produces this one when attempting to compile the snippet as /tmp/a-plus-b.rs:

10.4 Procedurally generated avatars from a multithreaded parser and code generator

This section applies the syntax that we learned in section 10.2 to an application. Let's say that we want the users of our app to have unique pictorial avatars by default. One approach for doing this is to take their usernames and the digest of a hash function, and then use those digits as parameter inputs to some procedural generation logic. Using this approach, everyone will have visually similar yet completely distinctive default avatars.

Our application creates parallax lines. It does this by using the characters within the Base 16 alphabet as opcodes for a LOGO-like language.

10.4.1 How to run render-hex and its intended output

In this section, we'll produce three variations. These will all be invoked in the same way. The following listing demonstrates this. It also shows the output from invoking our render-hex project (listing 10.18):

```
$ git clone https://github.com/rust-in-action/code rust-in-action
$ cd rust-in-action/ch10/ch10-render-hex
$ cargo run -- $(
> echo 'Rust in Action'
                               Generates some input from
   sha1sum |
                                the Base 16 alphabet
  cut -f1 -d' '
                                                        The project creates a
                               (e.g., 0-9 and A-F)
                                                        filename that matches
> )
                                                       the input data.
$ ls
5deaed72594aaa10edda990c5a5eed868ba8915e.svg Cargo.toml target
Cargo.lock
                                               src
                                                            Inspects the output
$ cat 5deaed72594aaa10edda990c5a5eed868ba8915e.svg
<svg height="400" style='style="outline: 5px solid #800000;"'</pre>
viewBox="0 0 400 400" width="400" xmlns="http://www.w3.org/2000/svg">
<rect fill="#ffffff" height="400" width="400" x="0" y="0"/>
<path d="M200,200 L200,400 L200,400 L200,400 L200,400 L200,400 L200,400 L200,</pre>
400 L480,400 L120,400 L-80,400 L560,400 L40,400 L40,400 L40,400 L40,400 L40,
400 L40,360 L200,200 L200,200 L200,200 L200,200 L200,200 L200,560 L200,

stroke-width="15" width="400" x="0" y="0"/>
</svq>
```

Any stream of valid Base 16 bytes generates a unique image. The file generated from echo 'Rust in Action' | sha256sum renders as shown in figure 10.4. To render SVG files, open the file in a web browser or a vector image program such as Inkscape (https://inkscape.org/).

10.4.2 Single-threaded render-hex overview

The render-hex project converts its input to an SVG file. The SVG file format succinctly describes drawings using mathematical operations. You can view the SVG file in any web browser and many graphics packages. Very little of the program relates to multithreading at this stage, so I'll skip much of the details. The program has a simple pipeline comprised of four steps:

- 1 Receives input from STDIN
- 2 Parses the input into operations that describe the movement of a pen across a sheet of paper
- 3 Converts the movement operations into its SVG equivalent
- 4 Generates an SVG file

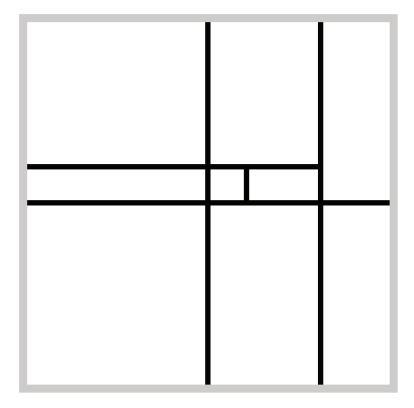

Figure 10.4 The SHA256 digest of Rust in Action displayed as a diagram

Why can't we directly create path data from input? Splitting this process into two steps allows for more transformations. This pipeline is managed directly within main().

The following listing shows the main() function for render-hex (listing 10.18). It parses the command-line arguments and manages the SVG generation pipeline. You'll find the source for this listing in ch10/ch10-render-hex/src/main.rs.

Listing 10.14 The main() function of render-hex

```
166 fn main() {
167
        let args = env::args().collect::<Vec<String>>();
                                                                 Command-line
168
        let input = args.get(1).unwrap();
                                                                 argument
        let default = format!("{}.svg", input);
169
                                                                 parsing
170
        let save to = args.get(2).unwrap or(&default);
171
     let operations = parse(input);
let path_data = convert(&operations);
172
173
                                                         SVG generation
174
       let document = generate_svg(path_data);
                                                         pipeline
175
        svg::save(save to, &document).unwrap();
176 }
```

INPUT PARSING

Our job in this section is to convert hexadecimal digits to instructions for a virtual pen that travels across a canvas. The Operation enum, shown in the following code snippet, represents these instructions.

NOTE The term *operation* is used rather than *instruction* to avoid colliding with the terminology used within the SVG specification for path drawing.

```
21 #[derive(Debug, Clone, Copy)]
22 enum Operation {
23    Forward(isize),
24    TurnLeft,
25    TurnRight,
26    Home,
27    Noop(usize),
28 }
```

To parse this code, we need to treat every byte as an independent instruction. Numerals are converted to distances, and letters change the orientation of the drawing:

```
In ASCII, numerals start at
                                                                   0x30 (48 in Base 10), so this
123 fn parse(input: &str) -> Vec<Operation> {
                                                                   converts the u8 value of b'2' to
                                                                   2. Performing this operation
124 let mut steps = Vec::<Operation>::new();
125 for byte in input.bytes() {
                                                                   on the whole range of u8
                                                                   could cause a panic, but
126
       let step = match byte {
                                                                   we're safe here, thanks to
         b'0' => Home,
127
                                                                   the guarantee provided by
         b'1'..=b'9' => {
                                                                  our pattern matching.
            let distance = (byte - 0x30) as isize;
129
             Forward(distance * (HEIGHT/10))
         },
131
                                                       There's plenty of opportunity
132
         b'a' | b'b' | b'c' => TurnLeft,
          b'd' | b'e' | b'f' => TurnRight,
                                                       to add more instructions to
133
                                                       produce more elaborate
           _ => Noop(byte),
                                                        diagrams without increasing
135
                                                       the parsing complexity.
136 };
137
       steps.push(step);
                                        Although we don't expect any illegal characters,
138
                                        there may be some in the input stream. Using a
139 steps
                                        Noop operation allows us to decouple parsing
140 }
                                        from producing output.
```

INTERPRET INSTRUCTIONS

The Artist struct maintains the state of the diagram. Conceptually, the Artist is holding a pen at the coordinates x and y and is moving it in the direction of heading:

```
49 #[derive(Debug)]
50 struct Artist {
51    x: isize,
52    y: isize,
53    heading: Orientation,
54 }
```

To move, Artist implements several methods of the render-hex project, two of which are highlighted in the following listing. Rust's match expressions are used to succinctly refer to and modify internal state. You'll find the source for this listing in ch10-render-hex/src/main.rs.

Listing 10.15 Moving Artist

```
70
     fn forward(&mut self, distance: isize) {
71
     match self.heading {
72
        North => self.y += distance,
        South => self.y -= distance,
73
        West => self.x += distance,
75
       East => self.x -= distance,
76
       }
     }
77
78
79
    fn turn right (&mut self) {
       self.heading = match self.heading {
80
        North => East,
81
82
        South => West,
83
       West => North,
       East => South,
85
86
     }
```

The convert () function in listing 10.16, an extract from the render-hex project (listing 10.18), makes use of the Artist struct. Its role is to convert the Vec<Operation> from parse() to a Vec<Command>. That output is used later to generate an SVG. As a nod to the LOGO language, Artist is given the local variable name turtle. The source for this listing is in ch10-render-hex/src/main.rs.

Listing 10.16 Focusing on the convert() function

```
131 fn convert(operations: &Vec<Operation>) -> Vec<Command> {
132
     let mut turtle = Artist::new();
133
     let mut path data: Vec<Command> = vec![];
                                                                 To start, positions
      let start at home = Command::Move(
                                                                 the turtle in the
135
          Position::Absolute, (HOME_X, HOME_Y).into()
                                                                 center of the
136
                                                                 drawing area
137
      path_data.push(start_at_home);
138
139
     for op in operations {
140
      match *op {
          Forward(distance) => turtle.forward(distance),
141
                                                                We don't generate a
142
         TurnLeft => turtle.turn left(),
                                                                Command immediately.
143
         TurnRight => turtle.turn right(),
                                                                Instead, we modify the
         Home => turtle.home(),
                                                               internal state of turtle.
144
145
          Noop(byte) => {
146
            eprintln!("warning: illegal byte encountered: {:?}", byte)
          },
147
148
        };
```

```
let line = Command::Line(
149
                                             Creates a Command::Line
         Position::Absolute,
150
                                             (a straight line toward the
151
         (turtle.x, turtle.y).into()
                                             turtle's current position)
      path_data.push(line);
153
154
155
       turtle.wrap(); <─
                                If the turtle is out of
156
                                  bounds, returns it to
157 path data
                                the center
158 }
```

GENERATING AN SVG

The process of generating the SVG file is rather mechanical. generate_svg() (lines 161–192 of listing 10.18) does the work.

SVG documents look a lot like HTML documents, although the tags and attributes are different. The <path> tag is the most important one for our purposes. It has a d attribute (d is short for data) that describes how the path should be drawn. convert () produces a Vec<Command> that maps directly to the path data.

Source code for the single-threaded version of render-hex

The render-hex project has an orthodox structure. The whole project sits within a (fairly large) main.rs file managed by cargo. To download the project's source code from its public code repository, use the following commands:

```
$ git clone https://github.com/rust-in-action/code rust-in-action
Cloning into 'rust-in-action'...
```

\$ cd rust-in-action/ch10/ch10-render-hex

Otherwise, to create the project by hand, follow the commands in the following snippet, and then copy the code from listing 10.18 into src/main.rs:

The standard project structure, which you can compare against the following snippet, has been created for you:

```
ch10-render-hex/
Cargo.toml
src
main.rs

See listing 10.17.

See listing 10.18.
```

The following listing shows the metadata for our project. You should check that your project's Cargo.toml matches the relevant details. You'll find the source for this listing in ch10/ch10-render-hex/Cargo.toml.

Listing 10.17 Project metadata for render-hex

```
[package]
name = "render-hex"
version = "0.1.0"
authors = ["Tim McNamara <author@rustinaction.com>"]
edition = "2018"
[dependencies]
svg = "0.6"
```

The single-threaded version of render-hex appears in the following listing. You'll find the source for this listing in ch10-render-hex/src/main.rs.

Listing 10.18 Source code for render-hex

```
1 use std::env;
 3 use svg::node::element::path::{Command, Data, Position};
 4 use svg::node::element::{Path, Rectangle};
 5 use svq::Document;
 7 use crate::Operation::{
   Forward,
 9
      Home,
10
     Noop,
                                     Operation and
11
      TurnLeft,
                                     Orientation enum
12
      TurnRight
                                     types are defined
13 };
                                     later. Including these
14 use crate::Orientation::{
                                     with the use keyword
                                     removes a lot of noise
15 East,
16
                                     from the source code.
     North,
17
     South,
     West
18
                                          HEIGHT and WIDTH provide
19 };
                                          the bounds of the drawing.
21 const WIDTH: isize = 400;
                                               HOME Y and HOME X constants allow
22 const HEIGHT: isize = WIDTH;
                                               us to easily reset where we are
                                               drawing from. Here y is the vertical
24 const HOME Y: isize = HEIGHT / 2;
                                            coordinate and x is the horizontal.
25 const HOME X: isize = WIDTH / 2;
                                               STROKE WIDTH, a parameter for
27 const STROKE WIDTH: usize = 5;
                                               the SVG output, defines the look of
28
                                               each drawn line.
```

```
29 #[derive(Debug, Clone, Copy)]
30 enum Orientation {
31
     North,
                        Using descriptions rather
32
     East,
                        than numerical values
33
     West,
                        avoids mathematics.
34
     South,
35 }
                                           To produce richer output,
36
                                           extends the operations
37 #[derive(Debug, Clone, Copy)]
                                           available to your programs
38 enum Operation {
     Forward(isize),
                                  Using isize lets us extend this example
40
     TurnLeft,
                                  to implement a Reverse operation
41
     TurnRight,
                                  without adding a new variant.
42
     Home,
43
     Noop(u8),
                            Uses Noop when we encounter illegal
44 }
                            input. To write error messages, we
45
                            retain the illegal byte.
46 #[derive(Debug)]
47 struct Artist {
                                  The Artist struct
     x: isize,
48
                                  maintains the
49
     y: isize,
                                  current state.
50

           self.heading = South;
109
110
111 }
                                                                 In ASCII, numerals start at
112
                                                                 0x30 (48). byte -0x30
113 fn parse(input: &str) -> Vec<Operation> {
                                                                 converts a u8 value of b'2' to
                                                                 2. Performing this operation
114
      let mut steps = Vec::<Operation>::new();
                                                                 on the whole range of u8
115
      for byte in input.bytes() {
                                                                 could cause a panic, but
116
        let step = match byte {
                                                                 we're safe here, thanks to
117
          b'0' => Home,
                                                                 the guarantee provided by
118
           b'1'..=b'9' => {
                                                                 our pattern matching.
             let distance = (byte - 0x30) as isize;
119
120
             Forward(distance * (HEIGHT / 10))
121
122
           b'a' | b'b' | b'c' => TurnLeft,
           b'd' | b'e' | b'f' => TurnRight,
123
           _ => Noop(byte),
124
                                        Although we don't expect any illegal
125
                                        characters, there may be some in
126
         steps.push(step);
                                        the input stream. A Noop operation
127
                                        allows us to decouple parsing from
128
      steps
                                        producing output.
129 }
130
131 fn convert(operations: &Vec<Operation>) -> Vec<Command> {
132
      let mut turtle = Artist::new();

196    let input = args.get(1).unwrap();
197    let default_filename = format!("{}.svg", input);
198    let save_to = args.get(2).unwrap_or(&default_filename);
199
200    let operations = parse(input);
201    let path_data = convert(&operations);
202    let document = generate_svg(path_data);
203    svg::save(save_to, &document).unwrap();
204 }
```

10.4.3 Spawning a thread per logical task

Our render-hex project (listing 10.18) also presents several opportunities for parallelism. We'll focus on one of these, the parse() function. To begin, adding parallelism is a two-step process:

- 1 Refactor code to use a functional style.
- 2 Use the rayon crate and its par iter() method.

USING A FUNCTIONAL PROGRAMMING STYLE

The first step in adding parallelism is to replace our for. Rather than for, the toolkit for creating a Vec<T> with functional programming constructs includes the map() and collect() methods and higher-order functions, typically created with closures.

To compare the two styles, consider the differences to the parse() function from listing 10.18 (in ch10-render-hex/src/main.rs), repeated in the following listing, and a more functional style in listing 10.20 (in ch10-render-hex-functional/src/main.rs).

Listing 10.19 Implementing parse () with imperative programming constructs

```
113 fn parse(input: &str) -> Vec<Operation> {
114  let mut steps = Vec::<Operation>::new();
for byte in input.bytes() {
    let step = match byte {
116
117
      b'0' => Home,
       b'1'..=b'9'=> {
         let distance = (byte - 0x30) as isize;
119
120
          Forward(distance * (HEIGHT / 10))
121
       b'a' | b'b' | b'c' => TurnLeft,
122
        b'd' | b'e' | b'f' => TurnRight,
123
         _ => Noop(byte),
124
125
126
      steps.push(step);
127 }
128
    steps
129 }
```

Listing 10.20 Implementing parse () with functional programming constructs

```
99 fn parse(input: &str) -> Vec<Operation> {
100 input.bytes().map(|byte|{
101 match byte {
       b'0' => Home
102
        b'1'..=b'9' => {
103
104
         let distance = (byte - 0x30) as isize;
105
          Forward(distance * (HEIGHT/10))
106
        },
         b'a' | b'b' | b'c' => TurnLeft,
107
         b'd' | b'e' | b'f' => TurnRight,
108
         _ => Noop(byte),
109
110 }}).collect()
111 }
```

Listing 10.20 is shorter, more declarative, and closer to idiomatic Rust. At a surface level, the primary change is that there is no longer a need to create the temporary variable steps. The partnership of map() and collect() removes the need for that: map() applies a function to every element of an iterator, and collect() stores the output of an iterator into a Vec<T>.

There is also a more fundamental change than eliminating temporary variables in this refactor, though. It has provided more opportunities for the Rust compiler to optimize your code's execution.

In Rust, iterators are an efficient abstraction. Working with their methods directly allows the Rust compiler to create optimal code that takes up minimal memory. As an example, the map() method takes a closure and applies it to every element of the iterator. Rust's trick is that map() also returns an iterator. This allows many transformations to be chained together. Significantly, although map() may appear in multiple places in your source code, Rust often optimizes those function calls away in the compiled binary.

When every step that the program should take is specified, such as when your code uses for loops, you restrict the number of places where the compiler can make decisions. Iterators provide an opportunity for you to delegate more work to the compiler. This ability to delegate is what will shortly unlock parallelism.

USING A PARALLEL ITERATOR

We're going to cheat here and make use of a crate from the Rust community: rayon. rayon is explicitly designed to add *data parallelism* to your code. Data parallelism applies the same function (or closure!) on different data (such as a Vec<T>).

Assuming that you've already worked with the base render-hex project, add rayon to your crate's dependencies with cargo by executing cargo add rayon@1:

Ensure that the [dependencies] section of your project's Cargo.toml matches the following listing. You'll find the source for this listing in ch10-render-hex-parallel-iterator/Cargo.toml.

Listing 10.21 Adding rayon as a dependency to Cargo.toml

```
7 [dependencies]
8 svg = "0.6.0"
9 rayon = "1"
```

At the head of the main.rs file, add rayon and its prelude as listing 10.23 shows. prelude brings several traits into the crate's scope. This has the effect of providing a par_bytes() method on string slices and a par_iter() method on byte slices. Those methods enable multiple threads to cooperatively process data. The source for this listing is in ch10-render-hex-parallel-iterator/Cargo.toml.

Listing 10.22 Adding rayon to our render-hex project

```
3 use rayon::prelude::*;
100 fn parse(input: &str) -> Vec<Operation> {
101 input
                                Converts the input string slice into a byte slice
104
     .map(|byte| match byte {
                               Converts the byte slice
      b'0' => Home,
105
                                into a parallel iterator
       b'1'..=b'9' => {
106
        let distance = (byte - 0x30) as isize;
107
108
         Forward(distance * (HEIGHT / 10))
109
       b'a' | b'b' | b'c' => TurnLeft,
110
111
       b'd' | b'e' | b'f' => TurnRight,
        112
113
                                whereas the Operation::Noop(u8)
114
      .collect()
                               variant requires a dereferenced value.
115 }
```

Using rayon's par_iter() here is a "cheat mode" available to all Rust programmers, thanks to Rust's powerful std::iter::Iterator trait. rayon's par_iter() is guaranteed to never introduce race conditions. But what should you do if you do not have an iterator?

10.4.4 Using a thread pool and task queue

Sometimes, we don't have a tidy iterator that we want to apply a function to. Another pattern to consider is the *task queue*. This allows tasks to originate anywhere and for the task processing code to be separated from task creation code. A fleet of worker threads can then pick tasks once these have finished their current one.

There are many approaches to modeling a task queue. We could create a Vec<Task> and Vec<Result> and share references to these across threads. To prevent each thread from overwriting each other, we would need a data protection strategy.

The most common tool to protect data shared between threads is Arc<Mutex<T>>. Fully expanded, that's your value T (e.g., Vec<Task> or Vec<Result> here) protected by a std::sync::Mutex, which itself is wrapped within std::sync::Arc. A Mutex is a mutually-exclusive lock. Mutually exclusive in this context means that no one has special rights. A lock held by any thread prevents all others. Awkwardly, a Mutex must itself be protected between threads. So we call in extra support. The Arc provides safe multithreaded access to the Mutex.

Mutex and Arc are not unified into a single type to provide programmers with added flexibility. Consider a struct with several fields. You may only need a Mutex on a single field, but you could put the Arc around the whole struct. This approach provides faster read access to the fields that are not protected by the Mutex. A single Mutex retains maximum protection for the field that has read-write access. The lock approach, while workable, is cumbersome. Channels offer a simpler alternative.

Channels have two ends: sending and receiving. Programmers don't get access to what is happening inside the channel. But placing data at the sending end means it'll appear at the receiving end at some future stage. Channels can be used as a task queue because multiple items can be sent, even if a receiver is not ready to receive any messages.

Channels are fairly abstract. These hide their internal structure, preferring to delegate access to two helper objects. One can send(); the other can recv() (receive). Importantly, we don't get access to *how* channels transmit any information sent through the channel.

NOTE By convention, from radio and telegraph operators, the Sender is called tx (shorthand for *transmission*) and the Receiver is called rx.

ONE-WAY COMMUNICATION

This section uses the channels implementation from the crossbeam crate rather than from the std::sync::mpsc module within the Rust standard library. Both APIs provide the same API, but crossbeam provides greater functionality and flexibility. We'll spend a little time explaining how to use channels. If you would prefer to see them used as a task queue, feel free to skip ahead.

The standard library provides a channels implementation, but we'll make use of the third-party crate, crossbeam. It provides slightly more features. For example, it includes both *bounded queues* and *unbounded queues*. A bounded queue applies *back pressure* under contention, preventing the consumer from becoming overloaded. Bounded queues (of fixed-width types) have deterministic maximum memory usage. These do have one negative characteristic, though. They force queue producers to wait until a space is available. This can make unbounded queues unsuitable for asynchronous messages, which cannot tolerate waiting.

The channels-intro project (listings 10.23 and 10.24) provides a quick example. Here is a console session that demonstrates running the channels-intro project from its public source code repository and providing its expected output:

```
$ git clone https://github.com/rust-in-action/code rust-in-action
Cloning into 'rust-in-action'...
$ cd ch10/ch10-channels-intro
$ cargo run
...
    Compiling ch10-channels-intro v0.1.0 (/ch10/ch10-channels-intro)
    Finished dev [unoptimized + debuginfo] target(s) in 0.34s
    Running `target/debug/ch10-channels-intro`
Ok(42)
```

To create the project by hand, follow these instructions:

1 Enter these commands from the command-line:

```
$ cargo new channels-intro
$ cargo install cargo-edit
$ cd channels-intro
$ cargo add crossbeam@0.7
```

- 2 Check that the project's Cargo.toml file matches listing 10.23.
- 3 Replace the contents of src/main.rs with listing 10.24.

The following two listings make up the project. Listing 10.23 shows its Cargo.toml file. Listing 10.24 demonstrates creating a channel for i32 messages from a worker thread.

Listing 10.23 Cargo.toml metadata for channels-intro

```
[package]
name = "channels-intro"
version = "0.1.0"
authors = ["Tim McNamara <author@rustinaction.com>"]
edition = "2018"

[dependencies]
crossbeam = "0.7"
```

Listing 10.24 Creating a channel that receives i32 messages

```
1 #[macro_use]
2 extern crate crossbeam;
3
4 use std::thread;
5 use crossbeam::channel::unbounded;
6
7
8 fn main() {
Provides the select!
macro, which simplifies
receiving messages
```

```
let (tx, rx) = unbounded();
9
10
11
      thread::spawn(move | | {
12
        tx.send(42)
13
            .unwrap();
                                  Provides the select!
14
      });
                                   macro, which simplifies
                                   receiving messages
      select!{
16
17
       recv(rx) -> msq => println!("{:?}", msq),
                                                             recv(rx) is syntax
18
                                                              defined by the macro.
19 }
```

Some notes about the channels-intro project:

- Creating a channel with crossbeam involves calling a function that returns Sender<T> and Receiver<T>. Within listing 10.24, the compiler infers the type parameter. tx is given the type Sender<i32> and rx is given the type Receiver<i32>.
- The select! macro takes its name from other messaging systems like the POSIX sockets API. It allows the main thread to block and wait for a message.
- Macros can define their own syntax rules. That is why the select! macro uses syntax
 (recv(rx) ->) that is not legal Rust.

WHAT CAN BE SENT THROUGH A CHANNEL?

Mentally, you might be thinking of a channel like you would envision a network protocol. Over the wire, however, you only have the type [u8] available to you. That byte stream needs to be parsed and validated before its contents can be interpreted.

Channels are richer than simply streaming bytes ([u8]). A byte stream is opaque and requires parsing to have structure extracted out of it. Channels offer you the full power of Rust's type system. I recommend using an enum for messages as it offers exhaustiveness testing for robustness and has a compact internal representation.

TWO-WAY COMMUNICATION

Bi-directional (duplex) communication is awkward to model with a single channel. An approach that's simpler to work with is to create two sets of senders and receivers, one for each direction.

The channels-complex project provides an example of this two channel strategy. channels-complex is implemented in listings 10.25 and 10.26. These are available in ch10/ch10-channels-complex/Cargo.toml and ch10/ch10-channels-complex/src/main.rs, respectively.

When executed, channels-complex produces three lines of output. Here is a session that demonstrates running the project from its public source code repository:

```
$ git clone https://github.com/rust-in-action/code rust-in-action
Cloning into 'rust-in-action'...
$ cd ch10/ch10-channels-complex
$ cargo run
...
```

```
Compiling ch10-channels-intro v0.1.0 (/ch10/ch10-channels-complex)
Finished dev [unoptimized + debuginfo] target(s) in 0.34s
Running `target/debug/ch10-channels-complex`
Ok(Pong)
Ok(Pong)
Ok(Pong)
```

Some learners prefer to type everything out by hand. Here are the instructions to follow if you are one of those people:

1 Enter these commands from the command-line:

```
$ cargo new channels-intro
$ cargo install cargo-edit
$ cd channels-intro
$ cargo add crossbeam@0.7
```

- 2 Check that the project's Cargo.toml matches listing 10.25.
- 3 Replace src/main.rs with the contents of listing 10.26.

Listing 10.25 Project metadata for channels-complex

```
[package]
name = "channels-complex"
version = "0.1.0"
authors = ["Tim McNamara <author@rustinaction.com>"]
edition = "2018"

[dependencies]
crossbeam = "0.7"
```

Listing 10.26 Sending messages to and from a spawned thread

```
1 #[macro use]
 2 extern crate crossbeam;
 4 use crossbeam::channel::unbounded;
 5 use std::thread;
 7 use crate::ConnectivityCheck::*;
 9 #[derive(Debug)]
10 enum ConnectivityCheck {
                                    Defining a bespoke
11 Ping,
                                   message type simplifies
12 Ponq,
                                   interpreting messages
13
     Pang,
                                   later.
14 }
15
16 fn main() {
17
   let n messages = 3;
     let (requests tx, requests rx) = unbounded();
18
     let (responses_tx, responses_rx) = unbounded();
19
20
```

```
21
    thread::spawn(move | loop {
                                                              Because all control flow
22
     match requests rx.recv().unwrap() {
                                                              is an expression, Rust
23
       Pong => eprintln!("unexpected pong response"),
                                                              allows the loop
       Ping => responses tx.send(Pong).unwrap(),
24
                                                             keyword here.
25
        Pang => return,
                                          The Pang message
26
                                         indicates the thread
27
     });
                                         should shut down.
28
29
     for _ in 0..n_messages {
30
     requests tx.send(Ping).unwrap();
31
32
    requests tx.send(Pang).unwrap();
33
34
    for _ in 0..n_messages {
     select! {
          recv(responses rx) -> msg => println!("{:?}", msg),
36
37
38
     }
39 }
```

IMPLEMENTING A TASK OUEUE

After spending some time discussing channels, it's time to apply these to the problem first introduced in listing 10.18. You'll notice that the code that follows shortly in listing 10.28 is quite a bit more complex than the parallel iterator approach seen in listing 10.24.

The following listing displays the metadata for the channel-based task queue implementation of render-hex. The source for this listing is in ch10/ch10-render-hex-threadpool/Cargo.toml.

Listing 10.27 The channel-based task queue metadata for render-hex

```
[package]
name = "render-hex"
version = "0.1.0"
authors = ["Tim McNamara <author@rustinaction.com>"]
edition = "2018"

[dependencies]
svg = "0.6"
crossbeam = "0.7" #
The crossbeam crate
is a new dependency
for the project.
```

The following listing focuses on the parse () function. The rest of the code is the same as listing 10.18. You'll find the code for the following listing in ch10/ch10-render-hex-threadpool/src/main.rs.

Listing 10.28 Partial code for the channel-based task queue for render-hex

```
1 use std::thread;
2 use std::env;
3
4 use crossbeam::channel::{unbounded};
```

```
99 enum Work {
                                                                                       Creates a type for the
                 100
                          Task((usize, u8)),
                                                                                       messages we send
                 101
                          Finished,
                                                                                       through the channels
                 102 }
                 103
                                                                                      The usize field of this tuple
                 104 fn parse byte(byte: u8) -> Operation {
                                                                                     indicates the position of the
                          match byte {
                105
                                                                                      processed byte. This is
                 106
                              b'0' => Home,
                                                                                     necessary because these can
                              b'1'..=b'9' => {
                 107
                                                                                     be returned out of order.
                 108
                                   let distance = (byte - 0x30) as isize;
                                                                                    Gives worker threads a
                 109
                                   Forward(distance * (HEIGHT/10))
                                                                                    marker message to indicate
                 110
                               },
                              b'a' | b'b' | b'c' => TurnLeft,
                                                                                    that it's time to shut down
                 111
                 112
                              b'd' | b'e' | b'f' => TurnRight,
                                                                                  Extracts the functionality that
                               _ => Noop(byte),
                 113
                                                                                  workers will need to carry out
                 114
                                                                                  to simplify the logic
                 115 }
Creates one
                 116
channel for
                 117 fn parse(input: &str) -> Vec<Operation> {
                                                                                     Creates one channel for
tasks to be
                 118
                          let n_threads = 2;
                                                                                     the decoded instructions
completed
                119
                          let (todo tx, todo rx) = unbounded();
                                                                                     to be returned to
                 120
                          let (results tx, results rx) = unbounded();
                 121
                          let mut n bytes = 0;
                                                                                          Fills the task
                 122
                          for (i,byte) in input.bytes().enumerate() {
                                                                                          queue with work
                               todo tx.send(Work::Task((i,byte))).unwrap();
                 123
                 124
                              n bytes += 1;
                                                                   Keeps track of how many
                 125
                                                                   tasks there are to do
                126
                          for in 0..n threads {
                 127
                                                                                 Sends each thread a
                 128
                              todo tx.send(Work::Finished).unwrap();
                                                                                 signal that it's time
                                                                                 to shut down
                 129
                 130
                          for _ in 0..n_threads {
                 131
                 132
                               let todo = todo rx.clone();
                                                                         When cloned, channels can
                 133
                               let results = results tx.clone();
                                                                       be shared between threads.
                 134
                               thread::spawn(move | | {
                 135
                                   loop {
                                        let task = todo.recv();
                 136
                 137
                                        let result = match task {
                                            Err( ) => break,
                138
                 139
                                            Ok(Work::Finished) => break,
                 140
                                            Ok(Work::Task((i, byte))) => (i, parse_byte(byte)),
                 141
                 142
                                        results.send(result).unwrap();
                                                                                   Because results can be
                 143
                                                                                   returned in arbitrary order,
                 144
                                                                                   initializes a complete
                               });
                 145
                                                                                   Vec < Command > that will
                                                                                  be overwritten by our
                 146
                                                                                   incoming results. We use a
                 147
                          let mut ops = vec! [Noop(0); n bytes];
                                                                                   vector rather than an array
                 148
                          for in 0...n bytes {
                                                                                   because that's what's used
                 149
                              let (i, op) = results rx.recv().unwrap();
                                                                                   by the type signature, and
                 150
                               ops[i] = op;
                                                                                   we don't want to refactor
                 151
                                                                                   the whole program to suit
                 152
                          ops
                                                                                   this new implementation.
                 153 }
```

When independent threads are introduced, the order in which tasks are completed becomes non-deterministic. Listing 10.28 includes some additional complexity to handle this.

Previously, we created an empty Vec<Command> for the commands that we interpreted from our input. Once parsed, main() repeatedly added elements via the vector's push() method. Now, at line 147, we fully initialize the vector. Its contents don't matter. It will all be overwritten. Even so, I've chosen to use Command::Noop to ensure that a mistake won't result in a corrupt SVG file.

10.5 Concurrency and task virtualization

This section explains the difference between models of concurrency. Figure 10.5 displays some of the trade-offs.

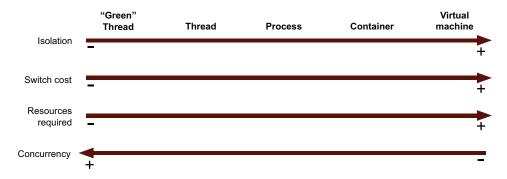

Figure 10.5 Trade-offs relating to different forms of task isolation in computing. In general terms, increasing the isolation level increases the overhead.

The primary benefit of more costly forms of task virtualization is isolation. What is meant by the term *isolation*?

Isolated tasks cannot interfere with each other. Interference comes in many forms. Examples include corrupting memory, saturating the network, and congestion when saving to disk. If a thread is blocked while waiting for the console to print output to the screen, none of the coroutines acting in that thread are able to progress.

Isolated tasks cannot access each other's data without permission. Independent threads in the same process share a memory address space, and all threads have equal access to data within that space. Processes, however, are prohibited from inspecting each other's memory.

Isolated tasks cannot cause another task to crash. A failure in one task should not cascade into other systems. If a process induces a kernel panic, all processes are shut down. By conducting work in virtual machines, tasks can proceed even when other tasks are unstable.

Isolation is a continuum. Complete isolation is impractical. It implies that input and output is impossible. Moreover, isolation is often implemented in software. Running extra software implies taking on extra runtime overhead.

A small glossary of terms relating to concurrency

This subfield is filled with jargon. Here is a brief introduction to some important terms and how we use them:

- Program—A program, or application, is a brand name. It's a name that we use
 to refer to a software package. When we execute a program, the OS creates a
 process.
- Executable—A file that can be loaded into memory and then run. Running an
 executable means creating a process and a thread for it, then changing the
 CPU's instruction pointer to the first instruction of the executable.
- Task—This chapter uses the term task in an abstract sense. Its meaning shifts as the level of abstraction changes:
 - a When discussing processes, a task is one of the process's threads.
 - **b** When referring to a thread, a task might be a function call.
 - When referring to an OS, a task might be a running program, which might be comprised of multiple processes.
- Process—Running programs execute as processes. A process has its own virtual address space, at least one thread, and lots of bookkeeping managed by the OS. File descriptors, environment variables, and scheduling priorities are managed per process. A process has a virtual address space, executable code, open handles to system objects, a security context, a unique process identifier, environment variables, a priority class, minimum and maximum working set sizes, and at least one thread of execution.

Each process is started with a single thread, often called the *primary thread*, but can create additional threads from any of its threads. Running programs begin their life as a single process, but it isn't uncommon to spawn subprocesses to do the work.

- Thread—The thread metaphor is used to hint that multiple threads can work together as a whole.
- Thread of execution—A sequence of CPU instructions that appear in serial.
 Multiple threads can run concurrently, but instructions within the sequence are intended to be executed one after another.
- Coroutine—Also known as fibre, green thread, and lightweight thread, a coroutine indicates tasks that switch within a thread. Switching between tasks becomes the responsibility of the program itself, rather than the OS. Two theoretical concepts are important to distinguish:
 - a Concurrency, which is multiple tasks of any level of abstraction running at the same time
 - Parallelism, which is multiple threads executing on multiple CPUs at the same time

(continued)

Outside of the fundamental terminology, there are also interrelated terms that appear frequently: asynchronous programming and non-blocking I/O. Many operating systems provide non-blocking I/O facilities, where data from multiple sockets is batched into queues and periodically polled as a group. Here are the definitions for these:

 Non-blocking I/O—Normally a thread is unscheduled when it asks for data from I/O devices like the network. The thread is marked as blocked, while it waits for data to arrive.

When programming with non-blocking I/O, the thread can continue executing even while it waits for data. But there is a contradiction. How can a thread continue to execute if it doesn't have any input data to process? The answer lies in asynchronous programming.

Asynchronous programming—Asynchronous programming describes programming for cases where the control flow is not predetermined. Instead, events outside the control of the program itself impact the sequence of what is executed. Those events are typically related to I/O, such as a device driver signalling that it is ready, or are related to functions returning in another thread.

The asynchronous programming model is typically more complicated for the developer, but results in a faster runtime for I/O-heavy workloads. Speed increases because there are fewer system calls. This implies fewer context switches between the user space and the kernel space.

10.5.1 Threads

A *thread* is the lowest level of isolation that an OS understands. The OS can schedule threads. Smaller forms of concurrency are invisible to the OS. You may have encountered terms such as coroutines, fibers, and green threads.

Switching between tasks here is managed by the process itself. The OS is ignorant of the fact that a program is processing multiple tasks. For threads and other forms of concurrency, context switching is required.

10.5.2 What is a context switch?

Switching between tasks at the same level of virtualization is known as a *context switch*. For threads to switch, CPU registers need to be cleared, CPU caches might need to be flushed, and variables within the OS need to be reset. As isolation increases, so does the cost of the context switch.

CPUs can only execute instructions in serial. To do more than one task, a computer, for example, needs to be able to press the Save Game button, switch to a new task, and resume at that task's saved spot. The CPU is *save scum*.

Why is the CPU constantly switching tasks? Because it has so much time available. Programs often need to access data from memory, disk, or the network. Because waiting for data is incredibly slow, there's often sufficient time to do something else in the meantime.

10.5.3 Processes

Threads exist within a process. The distinguishing characteristic of a process is that its memory is independent from other processes. The OS, in conjunction with the CPU, protects a process's memory from all others.

To share data between processes, Rust channels and data protected by Arc<Mutex<_>> won't suffice. You need some support from the OS. For this, reusing network sockets is common. Most operating systems provide specialized forms of interprocess communication (IPC), which are faster, while being less portable.

10.5.4 WebAssembly

WebAssembly (Wasm) is interesting because it is an attempt at isolating tasks within the process boundary itself. It's impossible for tasks running inside a Wasm module to access memory available to other tasks. Originating in web browsers, Wasm treats all code as potentially hostile. If you use third-party dependencies, it's likely that you haven't verified the behavior of all of the code that your process executes.

In a sense, Wasm modules are given access to address spaces within your process's address space. Wasm address spaces are called *linear memory*. Runtime interprets any request for data within linear memory and makes its own request to the actual virtual memory. Code within the Wasm module is unaware of any memory addresses that the process has access to.

10.5.5 Containers

Containers are extensions to processes with further isolation provided by the OS. Processes share the same filesystem, whereas containers have a filesystem created for them. The same is true for other resources, such as the network. Rather than address space, the term used for protections covering these other resources is *namespaces*.

10.5.6 Why use an operating system (OS) at all?

It's possible to run an application as its own OS. Chapter 11 provides one implementation. The general term for an application that runs without an OS is to describe it as *freestanding*—freestanding in the sense that it does not require the support of an OS. Freestanding binaries are used by embedded software developers when there is no OS to rely on.

Using freestanding binaries can involve significant limitations, though. Without an OS, applications no longer have virtual memory or multithreading. All of those concerns become your application's concerns. To reach a middle ground, it is possible to compile a *unikernel*. A unikernel is a minimal OS paired with a single application. The compilation process strips out everything from the OS that isn't used by the application that's being deployed.

Summary

- Closures and functions both feel like they should be the same type, but they aren't identical. If you want to create a function that accepts either a function or a closure as an argument, then make use of the std::ops::Fn family of traits.
- A functional style that makes heavy use of higher-order programming and iterators is idiomatic Rust. This approach tends to work better with third-party libraries because std::iter::Iterator is such a common trait to support.
- Threads have less impact than you have probably heard, but spawning threads without bounds can cause significant problems.
- To create a byte (u8) from a literal, use single quotes (e.g., b'a'). Double quotes (e.g., b"a") creates a byte slice ([u8]) of length 1.
- To increase the convenience of enums, it can be handy to bring their variants into local scope with use crate::.
- Isolation is provided as a spectrum. In general, as isolation between software components increases, performance decreases.

Kernel

This chapter covers

- Writing and compiling your own OS kernel
- Gaining a deeper understanding of the Rust compiler's capabilities
- Extending cargo with custom subcommands

Let's build an operating system (OS). By the end of the chapter, you'll be running your own OS (or, at least, a minimal subset of one). Not only that, but you will have compiled your own bootloader, your own kernel, and the Rust language directly for that new target (which doesn't exist yet).

This chapter covers many features of Rust that are important for programming without an OS. Accordingly, the chapter is important for programmers who intend to work with Rust on embedded devices.

11.1 A fledgling operating system (FledgeOS)

In this section, we'll implement an OS kernel. The OS kernel performs several important roles, such as interacting with hardware and memory management, and coordinating work. Typically, work is coordinated through processes and threads. We won't be able to cover much of that in this chapter, but we will get off the ground. We'll fledge, so let's call the system we're building *FledgeOS*.

366 CHAPTER 11 Kernel

11.11 Setting up a development environment for developing an OS kernel

Creating an executable for an OS that doesn't exist yet is a complicated process. For instance, we need to compile the core Rust language for the OS from your current one. But your current environment only understands your current environment. Let's extend that. We need several tools to help us out. Here are several components that you will need to install and/or configure before creating FledgeOS:

- QEMU—A virtualization technology. Formally part of a class of software called virtual machine monitors," it runs operating systems for any machine on any of its supported hosted architectures. Visit https://www.qemu.org/ for installation instructions.
- The bootimage crate and some supporting tools—The bootimage crate does the heavy lifting for our project. Thankfully, installing it and the tools needed to work with it effectively is a lightweight process. To do that, enter the following commands from the command line:

```
$ cargo install cargo-binutils
   Installed package `cargo-binutils v0.3.3` (executables `cargo-cov`,
   `cargo-nm`, `cargo-objcopy`, `cargo-objdump`, `cargo-profdata`,
   `cargo-readobj`, `cargo-size`, `cargo-strip`, `rust-ar`, `rust-cov`,
   `rust-ld`, `rust-lld`, `rust-nm`, `rust-objcopy`, `rust-objdump`,
   `rust-profdata`, `rust-readobj`, `rust-size`, `rust-strip`)
$ cargo install bootimage
   Installed package `bootimage v0.10.3` (executables `bootimage`,
   `cargo-bootimage`)
$ rustup toolchain install nightly
info: syncing channel updates for 'nightly-x86_64-unknown-linux-gnu'
$ rustup default nightly
info: using existing install for 'nightly-x86 64-unknown-linux-qnu'
info: default toolchain set to 'nightly-x86 64-unknown-linux-qnu'
$ rustup component add rust-src
info: downloading component 'rust-src'
                                                     Over time, this may
                                                     become the llvm-tools
                                                     component.
$ rustup component add llvm-tools-preview
info: downloading component 'llvm-tools-preview'
```

Each of these tools performs an important role:

• *The cargo-binutils crate*—Enables cargo to directly manipulate executable files via subcommands using utilities built with Rust and installed by cargo. Using

cargo-binutils rather than installing binutils via another route prevents any potential version mismatches.

- *The bootimage crate*—Enables cargo to build a *boot image*, an executable that can be booted directly on hardware.
- *The nightly toolchain*—Installing the nightly version of the Rust compiler unlocks features that have not yet been marked as stable, and thus constrained by Rust's backward-compatibility guarantees. Some of the compiler internals that we will be accessing in this chapter are unlikely to ever be stabilized.

We set nightly to be our default toolchain to simplify the build steps for projects in this chapter. To revert the change, use the command rustup default stable.

- *The rust-src component*—Downloads the source code for the Rust programming language. This enables Rust to compile a compiler for the new OS.
- *The llvm-tools-preview component*—Installs extensions for the LLVM compiler, which makes up part of the Rust compiler.

11.1.2 Verifying the development environment

To prevent significant frustration later on, it can be useful to double-check that everything is installed correctly. To do that, here's a checklist:

• *QEMU*—The qemu-system-x86_64 utility should be on your PATH. You can check that this is the case by providing the --version flag:

```
$ qemu-system-x86_64 --version
QEMU emulator version 4.2.1 (Debian 1:4.2-3ubuntu6.14)
Copyright (c) 2003-2019 Fabrice Bellard and the QEMU Project developers
```

• The cargo-binutils crate—As indicated by the output of cargo install cargo-binutils, several executables were installed on your system. Executing any of those with the --help flag should indicate that all of these are available. For example, to check that rust-strip is installed, use this command:

```
$ rust-strip --help
OVERVIEW: llvm-strip tool
USAGE: llvm-strip [options] inputs..
```

• *The bootimage crate*—Use the following command to check that all of the pieces are wired together:

```
$ cargo bootimage --help
Creates a bootable disk image from a Rust kernel
...
```

368 CHAPTER 11 Kernel

The llvm-tools-preview toolchain component—The LLVM tools are a set of auxiliary utilities for working with LLVM. On Linux and macOS, you can use the following commands to check that these are accessible to rustc:

```
$ export SYSROOT=$(rustc --print sysroot)

$ find "$SYSROOT" -type f -name 'llvm-*' -printf '%f\n' | sort
llvm-ar
llvm-as
llvm-cov
llvm-dis
llvm-nm
llvm-objcopy
llvm-objdump
llvm-profdata
llvm-readobj
llvm-size
llvm-strip
```

On MS Windows, the following commands produce a similar result:

```
C:\> rustc --print sysroot
C:\> cd <sysroot>
C:\> dir llvm*.exe /s /b

Replace <sysroot> with the output of the previous command
```

Great, the environment has been set up. If you encounter any problems, try reinstalling the components from scratch.

11.2 Fledgeos-0: Getting something working

FledgeOS requires some patience to fully comprehend. Although the code may be short, it includes many concepts that are probably novel because they are not exposed to programmers who make use of an OS. Before getting started with the code, let's see FledgeOS fly.

11.2.1 First boot

FledgeOS is not the world's most powerful operating system. Truthfully, it doesn't look like much at all. At least it's a graphical environment. As you can see from figure 11.1, it creates a pale blue box in the top-left corner of the screen.

To get fledgeos-0 up and running, execute these commands from a command-line prompt:

Figure 11.1 Expected output from running fledgeos-0 (listings 11.1-11.4)

Don't worry about *how* the block at the top left changed color. We'll discuss the retrocomputing details for that shortly. For now, success is being able to compile your own version of Rust, an OS kernel using that Rust, a bootloader that puts your kernel in the right place, and having these all work together.

Getting this far is a big achievement. As mentioned earlier, creating a program that targets an OS kernel that doesn't exist yet is complicated. Several steps are required:

- 1 Create a machine-readable definition of the conventions that the OS uses, such as the intended CPU architecture. This is the *target platform*, also known as a *compiler target* or simply *target*. You have seen targets before. Try executing rustup target list for a list that you can compile Rust to.
- 2 Compile Rust for the target definition to create the new target. We'll suffice with a subset of Rust called *core* that excludes the standard library (crates under std).
- 3 Compile the OS kernel for the new target using the "new" Rust.
- 4 Compile a bootloader that can load the new kernel.
- 5 Execute the bootloader in a virtual environment, which, in turn, runs the kernel.

Thankfully, the bootimage crate does all of this for us. With all of that fully automated, we're able to focus on the interesting pieces.

370 CHAPTER 11 Kernel

11.2.2 Compilation instructions

To make use of the publicly available source code, follow the steps in section 11.1.3. That is, execute these commands from a command prompt:

```
$ git clone https://github.com/rust-in-action/code rust-in-action
Cloning into 'rust-in-action'...
...
$ cd rust-in-action/ch11/ch11-fledgeos-0
```

To create the project by hand, here is the recommended process:

1 From a command-line prompt, execute these commands:

```
$ cargo new fledgeos-0
$ cargo install cargo-edit
$ cd fledgeos-0
$ mkdir .cargo
$ cargo add bootloader@0.9
$ cargo add x86_64@0.13
```

2 Add the following snippet to the end of project's Cargo.toml file. Compare the result with listing 11.1, which can be downloaded from ch11/ch11-fledgeos-0/Cargo.toml:

```
[package.metadata.bootimage]
build-command = ["build"]

run-command = [
   "qemu-system-x86_64", "-drive", "format=raw,file={}"
]
```

- 3 Create a new fledge.json file at the root of the project with the contents from listing 11.2. You can download this from the listing in ch11/ch11-fledgeos-0/fledge.json.
- 4 Create a new .cargo/config.toml file from listing 11.3, which is available in ch11/ch11-fledgeos-0/.cargo/config.toml.
- 5 Replace the contents of src/main with listing 11.4, which is available in ch11/ch11-fledgeos-0/src/main.rs.

11.2.3 Source code listings

The source code for the FledgeOS projects (code/ch11/ch11-fledgeos-*) uses a slightly different structure than most cargo projects. Here is a view of their layout, using fledgeos-0 as a representative example:

```
fledgeos-0

Cargo.toml

fledge.json

cargo

config.toml

See listing 11.1.

See listing 11.1.

See listing 11.1.
```

```
□ src
□ main.rs

See listing 11.4.
```

The projects include two extra files:

- *The project root directory contains a fledge.json file.* This is the definition of the compiler target that bootimage and friends will be building.
- *The .cargo/config.toml file provides extra configuration parameters.* These tell cargo that it needs to compile the std::core module itself for this project, rather than relying on it being preinstalled.

The following listing provides the project's Cargo.toml file. It is available in ch11/ch11-fledgeos-0/Cargo.toml.

Listing 11.1 Project metadata for fledgeos-0

```
[package]
name = "fledgeos"
version = "0.1.0"
authors = ["Tim McNamara <author@rustinaction.com>"]
edition = "2018"

[dependencies]
bootloader = "0.9"
x86_64 = "0.13"

[package.metadata.bootimage]
build-command = ["build"]

run-command = [
    "qemu-system-x86_64", "-drive", "format=raw,file={}"
Updates cargo run to invoke a
QEMU session. The path to the OS
image created during the build
replaces the curly braces ({}}).
```

The project's Cargo.toml file is slightly unique. It includes a new table, [package .metadata.bootimage], which contains a few directives that are probably confusing. This table provides instructions to the bootimage crate, which is a dependency of bootloader:

- bootimage—Creates a bootable disk image from a Rust kernel
- build-command—Instructs bootimage to use the cargo build command rather than cargo xbuild for cross-compiling
- run_command—Replaces the default behavior of cargo run to use QEMU rather than invoking the executable directly

TIP See the documentation at https://github.com/rust-osdev/bootimage/for more information about how to configure bootimage.

The following listing shows our kernel target's definition. It is available from ch11/ch11-fledgeos-0/fledge.json.

Listing 11.2 Kernel definition for FledgeOS

```
{
  "llvm-target": "x86_64-unknown-none",
  "data-layout": "e-m:e-i64:64-f80:128-n8:16:32:64-S128",
  "arch": "x86_64",
  "target-endian": "little",
  "target-pointer-width": "64",
  "target-c-int-width": "32",
  "os": "none",
  "linker": "rust-lld",
  "linker-flavor": "ld.lld",
  "executables": true,
  "features": "-mmx,-sse,+soft-float",
  "disable-redzone": true,
  "panic-strategy": "abort"
}
```

Among other things, the target kernel's definition specifies that it is a 64-bit OS built for x86-64 CPUs. This JSON specification is understood by the Rust compiler.

TIP Learn more about custom targets from the "Custom Targets" section of the rustc book at https://doc.rust-lang.org/stable/rustc/targets/custom.html.

The following listing, available from ch11/ch11-fledgeos-0/.cargo/config.toml, provides an additional configuration for building FledgeOS. We need to instruct cargo to compile the Rust language for the compiler target that we defined in the previous listing.

Listing 11.3 Extra build-time configuration for cargo

```
[build]
target = "fledge.json"

[unstable]
build-std = ["core", "compiler_builtins"]
build-std-features = ["compiler-builtins-mem"]

[target.'cfg(target_os = "none")']
runner = "bootimage runner"
```

We are finally ready to see the kernel's source code. The next listing, available from ch11/ch11-fledgeos-0/src/main.rs, sets up the boot process, and then writes the value 0x30 to a predefined memory address. You'll read about how this works in section 11.2.5.

Listing 11.4 Creating an OS kernel that paints a block of color

```
6 use core::panic::PanicInfo;
                                        Allows the panic handler
                                         to inspect where the
 8 #[panic handler]
                                         panic occurred
 9 #[no mangle]
10 pub fn panic( info: &PanicInfo) -> ! {
11 intrinsics::abort();
                                        Crashes the
12 }
                                       program
13
14 #[no mangle]
15 pub extern "C" fn start() -> ! {
16 let framebuffer = 0xb8000 as *mut u8;
17
                                  Increments the
18 unsafe {
     framebuffer
.offset(1)
                                pointer's address
19
                             by 1 to 0xb8001
20
21
        .write volatile(0x30);
                                       Sets the background
22
                                        to cyan
23
24
   loop {}
25 }
```

Listing 11.4 looks very different from the Rust projects that we have seen so far. Here are some of the changes to ordinary programs that are intended to be executed alongside an OS:

- *The central FledgeOS functions never return.* There is no place to return to. There are no other running programs. To indicate this, our functions' return type is the Never type (!).
- If the program crashes, the whole computer crashes. The only thing that our program can do when an error occurs is terminate. We indicate this by relying on LLVM's abort () function. This is explained in more detail in section 11.2.4.
- We must disable the standard library with ! [no_std]. As our application cannot rely on an OS to provide dynamic memory allocation, it's important to avoid any code that dynamically allocates memory. The ! [no_std] annotation excludes the Rust standard library from our crate. This has the side effect of preventing many types, such as Vec<T>, from being available to our program.
- We need to unlock the unstable core_intrinsics API with the #! [core_intrinsics] attribute. Part of the Rust compiler is provided by LLVM, the compiler produced by the LLVM project. LLVM exposes parts of its internals to Rust, which are known as intrinsic functions. As LLVM's internals are not subject to Rust's stability guarantees, there is always a risk that what is offered to Rust will change. Therefore, this implies that we must use the nightly compiler toolchain and explicitly opt into the unstable API in our program.
- We need to disable the Rust symbol-naming conventions with the #! [no_mangle] attribute. Symbol names are strings within the compiled binary. For multiple libraries to coexist at runtime, it's important that these names do not collide. Ordinarily, Rust avoids this by creating symbols via a process called name mangling. We need

to disable this from occurring in our program; otherwise, the boot process may fail.

- We should opt into C's calling conventions with extern "C". An operating system's calling convention relates to the way function arguments are laid out in memory, among other details. Rust does not define its calling convention. By annotating the _start() function with extern "C", we instruct Rust to use the C language's calling conventions. Without this, the boot process may fail.
- Writing directly to memory changes the display. Traditionally, operating systems used a simplistic model for adjusting the screen's output. A predefined block of memory, known as the *frame buffer*, was monitored by the video hardware. When the frame buffer changed, the display changed to match. One standard, used by our bootloader, is VGA (Video Graphics Array). The bootloader sets up address 0xb8000 as the start of the frame buffer. Changes to its memory are reflected onscreen. This is explained in detail in section 11.2.5.
- We should disable the inclusion of a main() function with the #! [no_main] attribute. The main() function is actually quite special because its arguments are provided by a function that is ordinarily included by the compiler (_start()), and its return values are interpreted before the program exits. The behavior of main() is part of the Rust runtime. Read section 11.2.6 for more details.

Where to go to learn more about OS development

The cargo bootimage command takes care of lots of nuisances and irritation. It provides a simple interface—a single command—to a complicated process. But if you're a tinkerer, you might like to know what's happening beneath the surface. In that case, you should search Philipp Oppermann's blog, "Writing an OS in Rust," at https://os.phil-opp.com/ and look into the small ecosystem of tools that has emerged from it at https://github.com/rust-osdev/.

Now that our first kernel is live, let's learn a little bit about how it works. First, let's look at panic handling.

11.2.4 Panic handling

Rust won't allow you to compile a program that doesn't have a mechanism to deal with panics. Normally, it inserts panic handling itself. This is one of the actions of the Rust runtime, but we started our code with #[no_std]. Avoiding the standard library is useful in that it greatly simplifies compilation, but manual panic handling is one of its costs. The following listing is an excerpt from listing 11.4. It introduces our panichandling functionality.

Listing 11.5 Focusing on panic handling for FledgeOS

- 1 #![no std]
- 2 #![no main]

```
3 #![feature(core_intrinsics)]
4
5 use core::intrinsics;
6 use core::panic::PanicInfo;
7
8 #[panic_handler]
9 #[no_mangle]
10 pub fn panic(_info: &PanicInfo) -> ! {
11 unsafe {
12 intrinsics::abort();
13 }
14 }
```

There is an alternative to intrinsics::abort(). We could use an infinite loop as the panic handler, shown in the following listing. The disadvantage of that approach is that any errors in the program trigger the CPU core to run at 100% until it is shut down manually.

Listing 11.6 Using an infinite loop as a panic handler

```
#[panic_handler]
#[no_mangle]
pub fn panic(_info: &PanicInfo) -> ! {
  loop { }
}
```

The PanicInfo struct provides information about where the panic originates. This information includes the filename and line number of the source code. It'll come in handy when we implement proper panic handling.

11.2.5 Writing to the screen with VGA-compatible text mode

The bootloader sets some magic bytes with raw assembly code in boot mode. At startup, the bytes are interpreted by the hardware. The hardware switches its display to an 80x25 grid. It also sets up a fixed-memory buffer that is interpreted by the hardware for printing to the screen.

VGA-compatible text mode in 20 seconds

Normally, the display is split into an 80x25 grid of cells. Each cell is represented in memory by 2 bytes. In Rust-like syntax, those bytes include several fields. The following code snippet shows the fields:

```
struct VGACell {
    is_blinking: u1,
    background_color: u3,
    is_bright: u1,
    character_color: u3,
    character: u8,
}

Available characters are drawn from the code page 437 encoding, which is (approximately) an extension of ASCII.
```

(continued)

VGA text mode has a 16-color palette, where 3 bits make up the main 8 colors. Foreground colors also have an additional bright variant, shown in the following:

This initialization at boot time makes it easy to display things onscreen. Each of the points in the 80x25 grid are mapped to locations in memory. This area of memory is called the *frame buffer*.

Our bootloader designates <code>0xb8000</code> as the start of a 4,000 byte frame buffer. To actually set the value, our code uses two new methods, <code>offset()</code> and <code>write_volatile()</code>, that you haven't encountered before. The following listing, an excerpt from listing <code>11.4</code>, shows how these are used.

Listing 11.7 Focusing on modifying the VGA frame buffer

```
18  let mut framebuffer = 0xb8000 as *mut u8;
19  unsafe {
20    framebuffer
21    .offset(1)
22    .write_volatile(0x30);
23  }
```

Here is a short explanation of the two new methods:

- Moving through an address space with offset ()—A pointer type's offset () method moves through the address space in increments that align to the size of the pointer. For example, calling .offset (1) on a *mut u8 (mutable pointer to a u8) adds 1 to its address. When that same call is made to a *mut u32 (mutable pointer to a u32), the pointer's address moves by 4 bytes.
- Forcing a value to be written to memory with write_volatile()—Pointers provide a write_volatile() method that issues a "volatile" write. Volatile prevents the compiler's optimizer from optimizing away the write instruction. A smart compiler might simply notice that we are using lots of constants everywhere and initialize the program such that the memory is simply set to the value that we want it to be.

The following listing shows another way to write framebuffer.offset(1).write_volatile(0x30). Here we use the dereference operator (*) and manually set the memory to 0x30.

Listing 11.8 Manually incrementing a pointer

```
18 let mut framebuffer = 0xb8000 as *mut u8;
19 unsafe {
20  *(framebuffer + 1) = 0x30;
21 }
Sets the memory location
0xb8001 to 0x30
```

The coding style from listing 11.8 may be more familiar to programmers who have worked heavily with pointers before. Using this style requires diligence. Without the aid of type safety provided by offset(), it's easy for a typo to cause memory corruption. The verbose coding style used in listing 11.7 is also friendlier to programmers with less experience performing pointer arithmetic. It declares its own intent.

11.2.6 _start(): The main() function for FledgeOS

An OS kernel does not include the concept of a main() function, in the sense that you're used to. For one thing, an OS kernel's main loop never returns. Where would it return to? By convention, programs return an error code when they exit to an OS. But operating systems don't have an OS to provide an exit code to. Secondly, starting a program at main() is also a convention. But that convention also doesn't exist for OS kernels. To start an OS kernel, we require some software to talk directly to the CPU. The software is called a *bootloader*.

The linker expects to see one symbol defined, _start, which is the program's *entry point*. It links start to a function that's defined by your source code.

In an ordinary environment, the _start() function has three jobs. Its first is to reset the system. On an embedded system, for example, _start() might clear registers and reset memory to 0. Its second job is to call main(). Its third is to call _exit(), which cleans up after main(). Our _start() function doesn't perform the last two jobs. Job two is unnecessary as the application's functionality is simple enough to keep within _start(). Job three is unnecessary, as is main(). If it were to be called, it would never return.

11.3 fledgeos-1: Avoiding a busy loop

Now that the foundations are in place, we can begin to add features to FledgeOS.

11.3.1 Being power conscious by interacting with the CPU directly

Before proceeding, FledgeOS needs to address one major shortcoming: it is extremely power hungry. The _start() function from listing 11.4 actually runs a CPU core at 100%. It's possible to avoid this by issuing the halt instruction (hlt) to the CPU.

The halt instruction, referred to as HLT in the technical literature, notifies the CPU that there's no more work to be done. The CPU resumes operating when an

interrupt triggers new action. As listing 11.9 shows, making use of the x84_64 crate allows us to issue instructions directly to the CPU. The listing, an excerpt of listing 11.10, makes use of the x86_64 crate to access the hlt instruction. It is passed to the CPU during the main loop of start() to prevent excessive power consumption.

Listing 11.9 Using the hlt instruction

```
7 use x86 64::instructions::{hlt};
17 #[no mangle]
18 pub extern "C" fn start() -> ! {
19 let mut framebuffer = 0xb8000 as *mut u8;
20 unsafe {
21 framebuffer
22
      .offset(1)
       .write_volatile(0x30);
2.3
24 }
25 loop {
26 hlt(); <---
                   This saves
27
                    electricity.
28 }
```

The alternative to using hlt is for the CPU to run at 100% utilization, performing no work. This turns your computer into a very expensive space heater.

11.3.2 fledgeos-1 source code

fledgeos-1 is mostly the same as fledgeos-0, except that its src/main.rs file includes the additions from the previous section. The new file is presented in the following listing and is available to download from code/ch11/ch11-fledgeos-1/src/main.rs. To compile the project, repeat the instructions in section 11.2.1, replacing references to fledgeos-0 with fledgeos-1.

Listing 11.10 Project source code for fledgeos-1

```
1 #![no std]
 2 #![no main]
 3 #![feature(core_intrinsics)]
5 use core::intrinsics;
 6 use core::panic::PanicInfo;
7 use x86 64::instructions::{hlt};
9 #[panic_handler]
10 #[no mangle]
11 pub fn panic( info: &PanicInfo) -> ! {
12 unsafe {
     intrinsics::abort();
13
14
   }
15 }
16
17 #[no mangle]
```

```
18 pub extern "C" fn _start() -> ! {
19    let mut framebuffer = 0xb8000 as *mut u8;
20    unsafe {
21      framebuffer
22      .offset(1)
23      .write_volatile(0x30);
24    }
25    loop {
26      hlt();
27    }
28 }
```

The x86_64 crate provided us with the ability to inject assembly instructions into our code. Another approach to explore is to use *inline assembly*. The latter approach is demonstrated briefly in section 12.3.

11.4 fledgeos-2: Custom exception handling

The next iteration of FledgeOS improves on its error-handling capabilities. FledgeOS still crashes when an error is triggered, but we now have a framework for building something more sophisticated.

11.4.1 Handling exceptions properly, almost

FledgeOS cannot manage any exceptions generated from the CPU when it detects an abnormal operation. To handle exceptions, our program needs to define an exception-handling personality function.

Personality functions are called on each stack frame as the stack is unwound after an exception. This means the call stack is traversed, invoking the personality function at each stage. The personality function's role is to determine whether the current stack frame is able to handle the exception. Exception handling is also known as *catching an exception*.

NOTE What is *stack unwinding*? When functions are called, stack frames accumulate. Traversing the stack in reverse is called *unwinding*. Eventually, unwinding the stack will hit start().

Because handling exceptions in a rigorous way is not necessary for FledgeOS, we'll implement only the bare minimum. Listing 11.11, an excerpt from listing 11.12, provides a snippet of code with the minimal handler. Inject it into main.rs. An empty function implies that any exception is fatal because none will be marked as the handler. When an exception occurs, we don't need to do anything.

Listing 11.11 Minimalist exception-handling personality routine

```
4 #![feature(lang_items)]

18 #[lang = "eh_personality"]
19 #[no_mangle]
20 pub extern "C" fn eh personality() { }
```

NOTE What is a *language item?* Language items are elements of Rust implemented as libraries outside of the compiler itself. As we strip away the standard library with #[no_std], we'll need to implement some of its functionality ourselves.

Admittedly, that's a lot of work to do nothing. But at least we can be comforted knowing that we are doing nothing in the right way.

11.4.2 fledgeos-2 source code

fledgeos-2 builds on fledgeos-0 and fledgeos-1. Its src/main.rs file includes the additions from the previous listing. The new file is presented in the following listing and is available to download from code/ch11/ch11-fledgeos-2/src/main.rs. To compile the project, repeat the instructions in section 11.2.1, replacing references to fledgeos-0 with fledgeos-2.

Listing 11.12 Source code for fledgeos-2

```
1 #![no std]

11.5 fledgeos-3: Text output

Let's write some text to the screen. That way, if we really do encounter a panic, we can report it properly. This section explains the process of sending text to the frame buffer in more detail. Figure 11.2 shows the output from running fledgeos-3.

Figure 11.2 Output produced by fledgeos-3

11.5.1 Writing colored text to the screen

To start, we'll create a type for the color numeric constants that are used later in listing 11.16. Using an enum rather than defining a series of const values provides enhanced type safety. In some sense, it adds a semantic relationship between the values. These are all treated as members of the same group.

The following listing defines an enum that represents the VGA-compatible text mode color palette. The mapping between bit patterns and colors is defined by the VGA standard, and our code should comply with it.

Listing 11.13 Representing related numeric constants as an enum

```
9 #[allow(unused)]
10 #[derive(Clone,Copy)]
11 #[repr(u8)]
12 enum Color {
13 Black = 0x0, White = 0xF,
14 Blue = 0x1, BrightBlue = 0x9,
15 Green = 0x2, BrightGreen = 0xA,
16 Cyan = 0x3, BrightCyan = 0xB,

We won't be using every color variant in our code, so we can silence warnings.

Opts into copy semantics

Instructs the compiler to use a single byte to represent the values
```

11.5.2 Controlling the in-memory representation of enums

We've been content to allow the compiler to determine how an enum is represented. But there are times when we need to pull in the reins. External systems often demand that our data matches their requirements.

Listing 11.13 provides an example of fitting the colors from the VGA-compatible text mode palette enum into a single u8. It removes any discretion from the compiler about which bit pattern (formally called the *discriminant*) to associate with particular variants. To prescribe a representation, add the repr attribute. You are then able to specify any integer type (i32, u8, i16, u16,...), as well as some special cases.

Using a prescribed representation has some disadvantages. In particular, it reduces your flexibility. It also prevents Rust from making space optimizations. Some enums, those with a single variant, require no representation. These appear in source code but occupy zero space in the running program.

11.5.3 Why use enums?

You could model colors differently. For instance, it's possible to create numeric constants that look identical in memory. The following shows one such possibility:

```
const BLACK: u8 = 0x0;
const BLUE: u8 = 0x1;
// ...
```

Using an enum adds an extra guard. It becomes much more difficult to use an illegal value in our code than if we were using an u8 directly. You will see this demonstrated when the Cursor struct is introduced in listing 11.17.

11.5.4 Creating a type that can print to the VGA frame buffer

To print to the screen, we'll use a Cursor struct that handles the raw memory manipulation and can convert between our Color type and what is expected by VGA. As the following listing shows, this type manages the interface between our code and the VGA frame buffer. This listing is another excerpt from listing 11.16.

Listing 11.14 Definition and methods for Cursor

```
25 struct Cursor {
26   position: isize,
27   foreground: Color,
28   background: Color,
29 }
30
```

```
31 impl Cursor {
                                                           Uses the foreground color as a
32
     fn color(&self) -> u8 {
                                                           base, which occupies the lower 4
33
       let fg = self.foreground as u8;
                                                           bits. Shift the background color
       let bg = (self.background as u8) << 4;</pre>
34
                                                           left to occupy the higher bits, then
35
       fg | bg
                                                           merge these together.
36
37
38
     fn print(&mut self, text: &[u8]) {
                                                        For expediency, the input uses
39
        let color = self.color();
                                                        a raw byte stream rather than
40
                                                        a type that guarantees the
41
       let framebuffer = 0xb8000 as *mut u8;
                                                        correct encoding.
42
       for &character in text {
43
         unsafe {
44
45
            framebuffer.offset(self.position).write volatile(character);
            framebuffer.offset(self.position + 1).write volatile(color);
46
47
48
          self.position += 2;
49
50
     }
51 }
```

11.5.5 Printing to the screen

Making use of Cursor involves setting its position and then sending a reference to Cursor.print(). The following listing, an excerpt from listing 11.16, expands the _start() function to also print to the screen.

Listing 11.15 Demonstrating printing to the screen

```
67 #[no_mangle]
68 pub extern "C" fn start() -> ! {
69
     let text = b"Rust in Action";
70
71
    let mut cursor = Cursor {
72
       position: 0,
73
       foreground: Color::BrightCyan,
74
       background: Color::Black,
75
     };
76
    cursor.print(text);
77
78
     loop {
79
      hlt();
80
     }
81 }
```

11.5.6 fledgeos-3 source code

fledgeos-3 continues to build on fledgeos-0, fledgeos-1, and fledgeos-2. Its src/main.rs file includes the additions from the this section. The complete file is presented in the following listing and is available to download from code/ch11/ch11-fledgeos-3/src/main.rs. To compile the project, repeat the instructions in section 11.2.1, replacing references to fledgeos-0 with fledgeos-3.

384 Chapter 11 Kernel

Listing 11.16 FledgeOS now prints text to the screen

```

10
11 #[allow(unused)]
12 #[derive(Clone, Copy)]
13 #[repr(u8)]
14 enum Color {
15 Black = 0x0, White = 0xF,
16 Blue = 0x1,
                   BrightBlue = 0x9,
17 Green = 0x2, BrightGreen = 0xA, 
18 Cyan = 0x3, BrightCyan = 0xB,
19 Red = 0x4,
                   BrightRed = 0xC,
20 Magenta = 0x5, BrightMagenta = 0xD,
21 Brown = 0x6,
                    Yellow = 0xE,
22 Gray = 0x7,
                    DarkGray = 0x8
23 }
24
25 struct Cursor {
26 position: isize,
    foreground: Color,
28
     background: Color,
29 }
30
31 impl Cursor {
32
    fn color(&self) -> u8 {
       let fg = self.foreground as u8;
33
34
      let bg = (self.background as u8) << 4;</pre>
35
       fg | bg
     }
36
37
38
     fn print(&mut self, text: &[u8]) {
     let color = self.color();
39
40
41
      let framebuffer = 0xb8000 as *mut u8;
42
43
     for &character in text {
44
        unsafe {
           framebuffer.offset(self.position).write volatile(character);
45
           framebuffer.offset(self.position + 1).write_volatile(color);
46
47
48
         self.position += 2;
49
50
51 }
52
53 #[panic handler]
```

```
54 #[no mangle]
55 pub fn panic( info: &PanicInfo) -> ! {
56 unsafe {
     intrinsics::abort();
58
59 }
60
61 #[lang = "eh personality"]
62 #[no mangle]
63 pub extern "C" fn eh personality() { }
65 #[no mangle]
66 pub extern "C" fn start() -> ! {
67 let text = b"Rust in Action";
69 let mut cursor = Cursor {
     position: 0,
70
     foreground: Color::BrightCyan,
71
     background: Color::Black,
72
73 };
74
    cursor.print(text);
75
76 loop {
77
     hlt();
78
79 }
```

11.6 fledgeos-4: Custom panic handling

Our panic handler, repeated in the following snippet, calls core::intrinsics::abort(). This shuts down the computer immediately, without providing any further input:

```
#[panic_handler]
#[no_mangle]
pub fn panic(_info: &PanicInfo) -> ! {
   unsafe {
     intrinsics::abort();
   }
}
```

11.6.1 Implementing a panic handler that reports the error to the user

For the benefit of anyone doing embedded development or wanting to execute Rust on microcontrollers, it's important to learn how to report where a panic occurs. A good place to start is with core::fmt::Write. That trait can be associated with the panic handler to display a message, as figure 11.3 shows.

11.6.2 Reimplementing panic() by making use of core::fmt::Write

The output shown by figure 11.3 is produced by listing 11.17. panic() now goes through a two-stage process. In the first stage, panic() clears the screen. The second stage involves the core::write! macro. core::write! takes a destination object as its

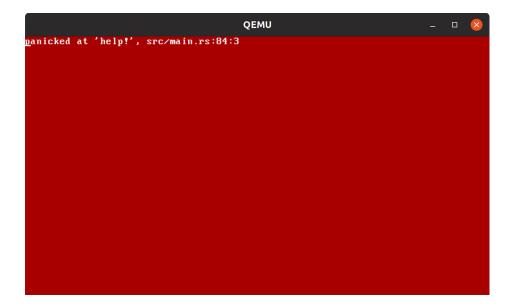

Figure 11.3 Displaying a message when a panic occurs

first argument (cursor), which implements the core::fmt::Write trait. The following listing, an excerpt from listing 11.19, provides a panic handler that reports that an error has occurred using this process.

Listing 11.17 Clearing the screen and printing the message

```
61 pub fn panic(info: &PanicInfo) -> ! {
62 let mut cursor = Cursor {
     position: 0,
63
      foreground: Color::White,
65
      background: Color::Red,
    };
66
    for in 0..(80*25) {
67
                                       Clears the screen by
68
     cursor.print(b" ");
                                       filling it with red
69
    cursor.position = 0;
70
                                                          Resets the position
     write!(cursor, "{}", info).unwrap();
71
                                                          of the cursor
72
73
                                                        Prints PanicInfo
                       Spins in an infinite loop, allowing
74 }
                                                      to the screen
                       the user to read the message and
                       restart the machine manually
```

11.6.3 Implementing core::fmt::Write

Implementing core::fmt::Write involves calling one method: write_str(). The trait defines several others, but the compiler can autogenerate these once an implementation of write_str() is available. The implementation in the following listing

reuses the print () method and converts the UTF-8 encoded &str into & [u8] with the to_bytes() method. The code for this listing is in ch11/ch11-fledgeos-4/src/main.rs.

Listing 11.18 Implementing core::fmt::Write for the Cursor type

```
54 impl fmt::Write for Cursor {
55   fn write_str(&mut self, s: &str) -> fmt::Result {
56     self.print(s.as_bytes());
57     Ok(())
58   }
59 }
```

11.6.4 fledge-4 source code

The following listing shows the user-friendly panic-handling code for FledgeOS. You'll find the source for this listing in ch11/ch11-fledgeos-4/src/main.rs. As with earlier versions, to compile the project, repeat the instructions at section 11.2.1 but replace references to fledgeos-0 with fledgeos-4.

Listing 11.19 Full code listing of FledgeOS with complete panic handling

Summary 389

Summary

Writing a program that is intended to run without an operating system can feel like programming in a barren desert. Functionality that you take for granted, such as dynamic memory or multithreading, is not available to you.

- In environments such as embedded systems that do not have dynamic memory management, you will need to avoid the Rust standard library with the #! [no_std] annotation.
- When interfacing with external components, naming symbols becomes significant. To opt out of Rust's name-mangling facilities, use the #! [no_mangle] attribute.
- Rust's internal representations can be controlled through annotations. For example, annotating an enum with #! [repr(u8]) forces the values to be packed into a single byte. If this doesn't work, Rust refuses to compile the program.
- Raw pointer manipulation is available to you, but type-safe alternatives exist. When it's practical to do so, use the offset () method to correctly calculate the number of bytes to traverse through the address space.
- The compiler's internals are always accessible to you at the cost of requiring a nightly compiler. Access compiler intrinsics like intrinsics::abort() to provide functionality to the program that's ordinarily inaccessible.
- cargo should be thought of as an extensible tool. It sits at the center of the Rust programmer's workflow, but its standard behavior can be changed when necessary.
- To access raw machine instructions, such as HTL, you can use helper crates like x86_64 or rely on inline assembly.
- Don't be afraid to experiment. With modern tools like QEMU, the worst that can happen is that your tiny OS crashes, and you'll need to run it again instantly.

Signals, interrupts, and exceptions

This chapter covers

- What interrupts, exceptions, traps, and faults are
- How device drivers inform applications that data is ready
- How to transmit signals between running applications

This chapter describes the process by which the outside world communicates with your operating system (OS). The network constantly interrupts program execution when bytes are ready to be delivered. This means that after connecting to a database (or at any other time), the OS can demand that your application deal with a message. This chapter describes this process and how to prepare your programs for it.

In chapter 9, you learned that a digital clock periodically notifies the OS that time has progressed. This chapter explains how those notifications occur. It also introduces the concept of multiple applications running at the same time via the concept of signals. Signals emerged as part of the UNIX OS tradition. These can be used to send messages between different running programs.

We'll address both concepts—signals and interrupts—together, as the programming models are similar. But it's simpler to start with signals. Although this chapter

Glossary 391

focuses on the Linux OS running on x86 CPUs, that's not to say that users of other operating systems won't be able to follow along.

12.1 Glossary

Learning how CPUs, device drivers, applications, and operating systems interact is difficult. There is a lot of jargon to take in. To make matters worse, the terms all look similar, and it certainly does not help that these are often used interchangeably. Here are some examples of the jargon that is used in this chapter. Figure 12.1 illustrates how these interrelate:

- Abort—An unrecoverable exception. If an application triggers an abort, the application terminates.
- Fault—A recoverable exception that is expected in routine operations such as a page fault. Page faults occur when a memory address is not available and data must be fetched from the main memory chip(s). This process is known as virtual memory and is explained in section 4 of chapter 6.
- *Exception*—Exception is an umbrella term that incudes aborts, faults, and traps. Formally referred to as *synchronous interrupts*, exceptions are sometimes described as a form of an interrupt.
- Hardware interrupt—An interrupt generated by a device such as a keyboard or hard disk controller. Typically used by devices to notify the CPU that data is available to be read from the device.
- Interrupt—A hardware-level term that is used in two senses. It can refer only to synchronous interrupts, which include hardware and software interrupts. Depending on context, it can also include exceptions. Interrupts are usually handled by the OS.
- Signal—An OS-level term for interruptions to an application's control flow. Signals are handled by applications.
- Software interrupt—An interrupt generated by a program. Within Intel's x86
 CPU family, programs can trigger an interrupt with the INT instruction. Among other uses of this facility, debuggers use software interrupts to set breakpoints.
- *Trap*—A recoverable exception such as an integer overflow detected by the CPU. Integer overflow is explained in section 5.2.

NOTE The meaning of the term *exception* may differ from your previous programming experience. Programming languages often use the term exception to refer to any error, whereas the term has a specialized meaning when referring to CPUs.

12.1.1 Signals vs. interrupts

The two concepts that are most important to distinguish between are signals and interrupts. A *signal* is a software-level abstraction that is associated with an OS. An *interrupt* is a CPU-related abstraction that is closely associated with the system's hardware.

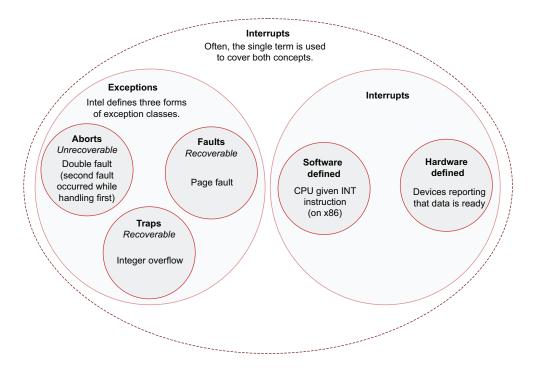

Figure 12.1 A visual taxonomy of how the terms interrupt, exception, trap, and fault interact within Intel's x86 family of CPUs. Note that signals do not appear within this figure. Signals are not interrupts.

Signals are a form of limited interprocess communication. They don't contain content, but their presence indicates something. They're analogous to a physical, audible buzzer. The buzzer doesn't provide content, but the person who presses it still knows what's intended as it makes a very jarring sound. To add confusion to the mix, signals are often described as software interrupts. This chapter, however, avoids the use of the term interrupt when referring to a signal.

There are two forms of interrupts, which differ in their origin. One form of interrupt occurs within the CPU during its processing. This is the result of attempting to process illegal instructions and trying to access invalid memory addresses. This first form is known technically as a *synchronous interrupt*, but you may have heard it referred to by its more common name, *exception*.

The second form of interrupt is generated by hardware devices like keyboards and accelerometers. This is what's commonly implied by the term interrupt. This can occur at any time and is formally known as an *asynchronous interrupt*. Like signals, this can also be generated within software.

Interrupts can be specialized. A *trap* is an error detected by the CPU, so it gives the OS a chance to recover. A *fault* is another form of a recoverable problem. If the CPU is given a memory address that it can't read from, it notifies the OS and asks for an updated address.

Interrupts force an application's control flow to change, whereas many signals can be ignored if desired. Upon receiving an interrupt, the CPU jumps to handler code, irrespective of the current state of the program. The location of the handler code is predefined by the BIOS and OS during a system's bootup process.

Treating signals as interrupts

Handling interrupts directly means manipulating the OS kernel. Because we would prefer not to do that in a learning environment, we'll play fast and loose with the terminology. The rest of this chapter, therefore, treats signals as interrupts.

Why simplify things? Writing OS components involves tweaking the kernel. Breaking things there means that our system could become completely unresponsive without a clear way to fix anything. From a more pragmatic perspective, avoiding tweaks to the kernel means that we'll avoid learning a whole new compiler toolchain.

To our advantage, code that handles signals looks similar to code that handles interrupts. Practicing with signals allows us to keep any errors within our code constrained to our application rather than risk bringing the whole system down. The general pattern is as follows:

- Model your application's standard control flow.
- 2 Model the interrupted control flow and identify resources that need to be cleanly shut down, if required.
- 3 Write the interrupt/signal handler to update some state and return quickly.
- 4 You will typically delegate time-consuming operations by only modifying a global variable that is regularly checked by the main loop of the program.
- 5 Modify your application's standard control flow to look for the GO/NO GO flag that a signal handler may have changed.

12.2 How interrupts affect applications

Let's work through this challenge by considering a small code example. The following listing shows a simple calculation that sums two integers.

<u>Listing 12.1 A program</u> that calculates the sum of two integers

```
1 fn add(a: i32, b:i32) -> i32 {
2    a + b
3 }
4
5 fn main() {
6   let a = 5;
7   let b = 6;
8   let c = add(a,b);
9 }
```

Irrespective of the number of hardware interrupts, c is always calculated. But the program's wall clock time becomes nondeterministic because the CPU performs different tasks every time it runs.

When an interrupt occurs, the CPU immediately halts execution of the program and jumps to the interrupt handler. The next listing (illustrated in figure 12.2) details what happens when an interrupt occurs between lines 7 and 8 in listing 12.1.

Listing 12.2 Depicting the flow of listing 12.1 as it handles an interrupt

```
1 #[allow(unused)]
 2 fn interrupt_handler() {
                                                 Although presented in
 3
      // ..
                                                 this listing as an extra
 4 }
                                                 function, the interrupt
 5
                                                 handler is typically
 6 fn add(a: i32, b:i32) -> i32 {
                                                 defined by the OS.
 7
      a + b
 8 }
 9
10 fn main() {
11
      let a = 5;
12
      let b = 6;
13
14
      // Key pressed on keyboard!
15
      interrupt handler()
16
17
      let c = add(a,b);
18 }
                 Normal program execution

program.
                                                                             other tasks, execution
                                                                             proceeds as normal.
                 add(a: i32, b: i32) -> i32
                                                 add(a: i32, b: i32) -> i32
                                                            a + b
                            a + b
```

Figure 12.2 Using addition to demonstrate control flow for handling signals

Return instruction is implicit in Rust.

RETURN

RETURN

One important point to remember is that, from the program's perspective, little changes. It isn't aware that its control flow has been interrupted. Listing 12.1 is still an accurate representation of the program.

12.3 Software interrupts

Software interrupts are generated by programs sending specific instructions to the CPU. To do this in Rust, you can invoke the asm! macro. The following code, available at ch12/asm.rs, provides a brief view of the syntax:

```
#![feature(asm)]
use std::asm;

fn main() {
    unsafe {
        asm!("int 42");
    }
}
```

Running the compiled executable presents the following error from the OS:

```
$ rustc +nightly asm.rs
$ ./asm
Segmentation fault (core dumped)
```

As of Rust 1.50, the asm! macro is unstable and requires that you execute the nightly Rust compiler. To install the nightly compiler, use rustup:

```
$ rustup install nightly
```

12.4 Hardware interrupts

Hardware interrupts have a special flow. Devices interface with a specialized chip, known as the *Programmable Interrupt Controller (PIC)*, to notify the CPU. Figure 12.3 provides a view of how interrupts flow from hardware devices to an application.

12.5 Signal handling

Signals require immediate attention. Failing to handling a signal typically results in the application being terminated.

12.5.1 Default behavior

Sometimes the best approach is to let the system's defaults do the work. Code that you don't need to write is code that's free from bugs that you inadvertently cause.

The default behavior for most signals is shutting down the application. When an application does not provide a special handler function (we'll learn how to do that in this chapter), the OS considers the signal to be an *abnormal* condition. When an OS detects an abnormal condition within an application, things don't end well for the application—it terminates the application. Figure 12.4 depicts this scenario.

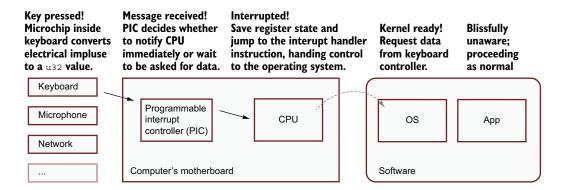

Figure 12.3 How applications are notified of an interrupt generated from a hardware device. Once the OS has been notified that data is ready, it then directly communicates with the device (in this case, the keyboard) to read the data into its own memory.

Figure 12.4 An application defending itself from marauding hoards of unwanted signals. Signal handlers are the friendly giants of the computing world. They generally stay out of the way but are there when your application needs to defend its castle. Although not part of everyday control flow, signal handlers are extremely useful when the time is right. Not all signals can be handled. SIGKILL is particularly vicious.

Your application can receive three common signals. The following lists them and their intended actions:

- SIGINT—Terminates the program (usually generated by a person)
- SIGTERM—Terminates the program (usually generated by another program)
- SIGKILL—Immediately terminates the program without the ability to recover

You'll find many other less common signals. For your convenience, a fuller list is provided in table 12.2.

You may have noticed that the three examples listed here are heavily associated with terminating a running program. But that's not necessarily the case.

12.5.2 Suspend and resume a program's operation

There are two special signals worth mentioning: SIGSTOP and SIGCONT. SIGSTOP halts the program's execution, and it remains suspended until it receives SIGCONT. UNIX systems use this signal for job control. It's also useful to know about if you want to manually intervene and halt a running application but would like the ability to recover at some time in the future.

The following snippet shows the structure for the sixty project that we'll develop in this chapter. To download the project, enter these commands in the console:

```
$ git clone https://github.com/rust-in-action/code rust-in-action
$ cd rust-in-action/ch12/ch12-sixty
```

To create the project manually, set up a directory structure that resembles the following and populate its contents from listings 12.3 and 12.4:

```
ch12-sixty

src
main.rs
Cargo.toml

See listing 12.4.

See listing 12.3.
```

The following listing shows the initial crate metadata for the sixty project. The source code for this listing is in the ch12/ch12-sixty/ directory.

Listing 12.3 Crate metadata for the sixty project

```
[package]
name = "sixty"
version = "0.1.0"
authors = ["Tim McNamara <author@rustinaction.com>"]
[dependencies]
```

The next listing provides the code to build a basic application that lives for 60 seconds and prints its progress along the way. You'll find the source for this listing in ch12/ch12-sixty/src/main.rs.

Listing 12.4 A basic application that receives SIGSTOP and SIGCONT

```
1 use std::time;
2 use std::process;
3 use std::thread::{sleep};
4
5 fn main() {
6
     let delay = time::Duration::from secs(1);
7
8
    let pid = process::id();
    println!("{}", pid);
9
10
11 for i in 1..=60 {
12
      sleep(delay);
```

Once the code from listing 12.4 is saved to disk, two consoles open. In the first, execute cargo run. A 3–5 digit number appears, followed by a counter that increments by the second. The first line number is the *PID* or *process ID*. Table 12.1 shows the operation and expected output.

Table 12.1 How processes can be suspended and resumed with SIGSTOP and SIGCONT

Step	Console 1	Console 2		
	Executes application	Sends signals		
1	\$ cd ch12/ch12-sixty			
2	<pre>\$ cargo run 23221 . 1 . 2 . 3 . 4</pre>			
3		\$ kill -SIGSTOP 23221		
4	[1]+ Stopped cargo run \$			
5		\$ kill -SIGCONT 23221		
6	. 5 . 6 . 7 . 8			
	. 60			

The program flow in table 12.1 follows:

- 1 In console 1, move to the project directory (created from listings 12.3 and 12.4).
- 2 Compile and run the project.

cargo provides debugging output that is omitted here. When running, the sixty program prints the PID, and then prints some numbers to the console every second. Because it was the PID for this invocation, 23221 appears as output in the table.

3 In console 2, execute the kill command, specifying -SIGSTOP.

If you are unfamiliar with the shell command kill, its role is to send signals. It's named after its most common role, terminating programs with either SIGKILL

or SIGTERM. The numeric argument (23221) must match the PID provided in step 2.

- 4 Console 1 returns to the command prompt as there is no longer anything running in the foreground.
- **5** Resume the program by sending SIGCONT to the PID provided in step 2.
- 6 The program resumes counting. It terminates when it hits 60, unless interrupted by Ctrl-C (SIGINT).

SIGSTOP and SIGCONT are interesting special cases. Let's continue by investigating more typical signal behavior.

12.5.3 Listing all signals supported by the OS

What are the other signals and what are their default handlers? To find the answer, we can ask the kill command to provide that information:

			_	I stands for list.						
\$ kill -l			<	i stailus ioi iist.						
	1)	SIGHUP	2)	SIGINT	3)	SIGQUIT	4)	SIGILL	5)	SIGTRAP
	6)	SIGABRT	7)	SIGEMT	8)	SIGFPE	9)	SIGKILL	10)	SIGBUS
	11)	SIGSEGV	12)	SIGSYS	13)	SIGPIPE	14)	SIGALRM	15)	SIGTERM
	16)	SIGURG	17)	SIGSTOP	18)	SIGTSTP	19)	SIGCONT	20)	SIGCHLD
	21)	SIGTTIN	22)	SIGTTOU	23)	SIGIO	24)	SIGXCPU	25)	SIGXFSZ
	26)	SIGVTALRM	27)	SIGPROF	28)	SIGWINCH	29)	SIGPWR	30)	SIGUSR1
	31)	SIGUSR2	32)	SIGRTMAX						

That's a lot, Linux! To make matters worse, few signals have standardized behavior. Thankfully, most applications don't need to worry about setting handlers for many of these signals (if any). Table 12.1 shows a much tighter list of signals. These are more likely to be encountered in day-to-day programming.

Table 12.2 List of common signals, their default actions, and shortcuts for sending them from the command line

Signal	Read as	Default action	Comment	Shortcut
SIGHUP	Hung up	Terminate	Originally from telephone- based digital communications. Now often sent to background applications (daemons/ser- vices) to request that these reread their configuration files. Sent to running pro- grams when you log out from a shell.	Ctrl-D
SIGINT	Interrupt (or per- haps interactive)	Terminate	User-generated signal to terminate a running application.	Ctrl-C
SIGTERM	Terminate	Terminate	Asks application to gracefully terminate.	

Signal	Read as	Default action	Comment	Shortcut
SIGKILL	Kill	Terminate	This action is unstoppable.	
SIGQUIT	Quit		Writes memory to disk as a core dump, then terminates.	Ctrl-\
SIGTSTP	Terminal stop	Pause execution	The terminal requests the application to stop.	Ctrl-Z
SIGSTOP	Stop	Pause execution	This action is unstoppable.	
SIGCONT	Continue	Resume execution when paused		

Table 12.2 List of common signals, their default actions, and shortcuts for sending them from the command line (continued)

NOTE SIGKILL and SIGSTOP have special status: these cannot be handled or blocked by the application. Programs can avoid the others.

12.6 Handling signals with custom actions

The default actions for signals are fairly limited. By default, receiving a signal tends to end badly for applications. For example, if external resources such as database connections are left open, they might not be cleaned up properly when the application ends.

The most common use case for signal handlers is to allow an application to shut down cleanly. Some common tasks that might be necessary when an application shuts down include

- Flushing the hard disk drive to ensure that pending data is written to disk
- Closing any network connections
- Deregistering from any distributed scheduler or work queue

To stop the current workload and shut down, a signal handler is required. To set up a signal handler, we need to create a function with the signature f(i32) -> (). That is, the function needs to accept an i32 integer as its sole argument and returns no value.

This poses some software engineering issues. The signal handler isn't able to access any information from the application except which signal was sent. Therefore, because it doesn't know what state anything is in, it doesn't know what needs shutting down beforehand.

There are some additional restrictions in addition to the architectural one. Signal handlers are constrained in time and scope. These must also act quickly within a subset of functionality available to general code for these reasons:

- Signal handlers can block other signals of the same type from being handled.
- Moving fast reduces the likelihood of operating alongside another signal handler of a different type.

Signal handlers have reduced scope in what they're permitted to do. For example, they must avoid executing any code that might itself generate signals.

To wriggle out of this constrained environment, the ordinary approach is to use a Boolean flag as a global variable that is regularly checked during a program's execution. If the flag is set, then you can call a function to shutdown the application cleanly within the context of the application. For this pattern to work, there are two requirements:

- The signal handler's sole responsibility is to mutate the flag.
- The application must regularly check the flag to detect whether the flag has been modified.

To avoid race conditions caused by multiple signal handlers running at the same time, signal handlers typically do little. A common pattern is to set a flag via a global variable.

12.6.1 Global variables in Rust

Rust facilitates *global variables* (variables accessible anywhere within the program) by declaring a variable with the static keyword in global scope. Suppose we want to create a global value SHUT_DOWN that we can set to true when a signal handler believes it's time to urgently shut down. We can use this declaration:

```
static mut SHUT DOWN: bool = false;
```

NOTE static mut is read as *mutable static*, irrespective of how grammatically contorted that is.

Global variables present an issue for Rust programmers. Accessing these (even just for reading) is unsafe. This means that the code can become quite cluttered if it's wrapped in unsafe blocks. This ugliness is a signal to wary programmers—avoid global state whenever possible.

Listing 12.6 presents a example of a static mut variable that reads from line 12 and writes to lines 7–9. The call to rand::random() on line 8 produces Boolean values. Output is a series of dots. About 50% of the time, you'll receive output that looks like what's shown in the following console session:¹

```
$ git clone https://github.com/rust-in-action/code rust-in-action
$ cd rust-in-action/ch12/ch2-toy-global
$ cargo run -q
```

The following listing provides the metadata for listing 12.6. You can access its source code in ch12/ch12-toy-global/Cargo.toml.

¹ Output assumes a fair random number generator, which Rust uses by default. This assumption holds as long as you trust your operating system's random number generator.

Listing 12.5 Crate metadata for listing 12.6

```
[package]
name = "ch12-toy-global"
version = "0.1.0"
authors = ["Tim McNamara <author@rustinaction.com>"]
edition = "2018"

[dependencies]
rand = "0.6"
```

The following listing presents our toy example. Its source code is in ch12/ch12-toy-global/src/main.rs.

Listing 12.6 Accessing global variables (mutable statics) in Rust

```
1 use rand;
 3 static mut SHUT DOWN: bool = false;
                                          Reading from and writing
 5 fn main() {
                                          to a static mut variable
 6 loop {
                                          requires an unsafe block.
 7
       unsafe {
          SHUT DOWN = rand::random();
 8
                                                     rand::random() is a shortcut that
 9
                                                     calls rand::thread rng().gen() to
10
      print!(".");
                                                     produce a random value. The
11
                                                     required type is inferred from
       if unsafe { SHUT DOWN } {
12
                                                     the type of SHUT DOWN.
13
        break
14
       };
15
16
     println!()
17 }
```

12.6.2 Using a global variable to indicate that shutdown has been initiated

Given that signal handlers must be quick and simple, we'll do the minimal amount of possible work. In the next example, we'll set a variable to indicate that the program needs to shut down. This technique is demonstrated by listing 12.8, which is structured into these three functions:

- register_signal_handlers()—Communicates to the OS via libc, the signal handler for each signal. This function makes use of a function pointer, which treats a function as data. Function pointers are explained in section 11.7.1.
- handle_signals()—Handles incoming signals. This function is agnostic as to which signal is sent, although we'll only deal with SIGTERM.
- main()—Initializes the program and iterates through a main loop.

When run, the resulting executable produces a trace of where it is. The following console session shows the trace:

NOTE If the signal handler is not correctly registered, Terminated may appear in the output. Make sure that you add a call to register_signal_handler() early within main(). Listing 12.8 does this on line 38.

The following listing shows the package and dependency for listing 12.8. You can view the source for this listing in ch12/ch12-basic-handler/Cargo.toml.

Listing 12.7 Crate setup for listing 12.10

```
[package]
name = "ch12-handler"
version = "0.1.0"
authors = ["Tim McNamara <author@rustinaction.com>"]
edition = "2018"
[dependencies]
libc = "0.2"
```

When executed, the following listing uses a signal handler to modify a global variable. The source for this listing is in ch12/ch12-basic-handler/src/main.rs.

Listing 12.8 Creating a signal handler that modifies a global variable

```
1 #![cfq(not(windows))]
                                      Indicates that
                                       this code won't
 3 use std::time::{Duration};
                                       run on Windows
 4 use std::thread::{sleep};
 5 use libc::{SIGTERM, SIGUSR1};
 7 static mut SHUT DOWN: bool = false;
                                              Must occur as soon as
 8
                                              possible; otherwise signals
 9 fn main() {
                                             will be incorrectly handled
10
   register signal handlers();
11
12
     let delay = Duration::from secs(1);
13
14
   for i in 1 usize.. {
15
      println!("{}", i);
16
       unsafe {
                                   Accessing a
        if SHUT_DOWN {
17
                                   mutable static
           println!("*");
                                   is unsafe.
```

```
19
                            return;
                20
                21
                        }
                22
                23
                        sleep(delay);
                24
                        let signal = if i > 2 {
                2.5
                26
                          SIGTERM
                27
                        } else {
                        SIGUSR1
                28
                29

                                                                      changes affecting
    called.
                54 }
                                                                      the signal
                55
                                                                      handler itself
              ⇒ 56 #[allow(dead code)]
                57 fn handle sigusr1( signal: i32) {
                     register signal handlers();
                59
                60
                     println!("SIGUSR1");
                61 }
```

In the preceding listing, there is something special about the calls to libc::signal() on lines 40 and 41. libc::signal takes a signal name (which is actually an integer) and an untyped function pointer (known in C parlance as a *void function pointer*) as arguments and associates the signal with the function. Rust's fn keyword creates function pointers. handle_sigterm() and handle_sigusr1() both have the type fn(i32) -> (). We need to cast these as usize values to erase any type information. Function pointers are explained in more detail in section 12.7.1.

Understanding the difference between const and static

Static and constant seem similar. Here is the main difference between them:

- static values appear in a single location in memory.
- const values can be duplicated in locations where they are accessed.

Duplicating const values can be a CPU-friendly optimization. It allows for data locality and improved cache performance.

Why use confusingly similar names for two different things? It could be considered a historical accident. The word static refers to the segment of the address space that the variables live in. static values live outside the stack space, within the region where string literals are held, near the bottom of the address space. That means accessing a static variable almost certainly implies dereferencing a pointer.

The constant in const values refers to the value itself. When accessed from code, the data might get duplicated to every location that it's needed if the compiler believes that this will result in faster access.

12.7 Sending application-defined signals

Signals can be used as a limited form of messaging. Within your business rules, you can create definitions for SIGUSR1 and SIGUSR2. These are unallocated by design. In listing 12.8, we used SIGUSR1 to do a small task. It simply prints the string SIGUSR1. A more realistic use of custom signals is to notify a peer application that some data is ready for further processing.

12.7.1 Understanding function pointers and their syntax

Listing 12.8 includes some syntax that might be confusing. For example, on line 40 handle_sigterm as usize appears to cast a function as an integer.

What is happening here? The address where the function is stored is being converted to an integer. In Rust, the fn keyword creates a function pointer.

Readers who have worked through chapter 5 will understand that functions are just data. That is to say, functions are sequences of bytes that make sense to the CPU. A *function pointer* is a pointer to the start of that sequence. Refer back to chapter 5, especially section 5.7, for a refresher.

A *pointer* is a data type that acts as a stand-in for its referent. Within an application's source code, pointers contain both the address of the value referred to as well as its type. The type information is something that's stripped away in the compiled binary. The internal representation for pointers is an integer of usize. That makes pointers very economical to pass around. In C, making use of function pointers can feel like arcane magic. In Rust, they hide in plain sight.

Every fn declaration is actually declaring a function pointer. That means that listing 12.9 is legal code and should print something similar to the following line:

```
$ rustc ch12/fn-ptr-demo-1.rs && ./fn-ptr-demo-1
noop as usize: 0x5620bb4af530
```

NOTE In the output, 0x5620bb4af530 is the memory address (in hexadecimal notation) of the start of the noop() function. This number will be different on your machine.

The following listing, available at ch12/noop.rs, shows how to cast a function to usize. This demonstrates how usize can be used as a function pointer.

Listing 12.9 Casting a function to usize

```
fn noop() {}
fn main() {
   let fn_ptr = noop as usize;
   println!("noop as usize: 0x{:x}", fn_ptr);
}
```

But what is the type of the function pointer created from fn noop()? To describe function pointers, Rust reuses its function signature syntax. In the case of fn noop(), the type is *const fn() -> (). This type is read as "a const pointer to a function that takes no arguments and returns unit." A const pointer is immutable. A unit is Rust's stand-in value for "nothingness."

Listing 12.10 casts a function pointer to usize and then back again. Its output, shown in the following snippet, should show two lines that are nearly identical:

```
$ rustc ch12/fn-ptr-demo-2.rs && ./fn-ptr-demo-2
noop as usize: 0x55ab3fdb05c0
noop as *const T: 0x55ab3fdb05c0
```

NOTE These two numbers will be different on your machine, but the two numbers will match each other.

Listing 12.10 Casting a function to usize

12.8 Ignoring signals

As noted in table 12.2, most signals terminate the running program by default. This can be somewhat disheartening for the running program attempting to get its work done. (Sometimes the application knows best!) For those cases, many signals can be ignored.

SIGSTOP and SIGKILL aside, the constant SIG_IGN can be provided to libc:: signal() instead of a function pointer. An example of its usage is provided by the ignore project. Listing 12.11 shows its Cargo.toml file, and listing 12.12 shows src/main.rs. These are both available from the ch12/ch12-ignore project directory. When executed, the project prints the following line to the console:

```
$ cd ch12/ch12-ignore
$ cargo run -q
ok
```

The ignore project demonstrates how to ignore selected signals. On line 6 of listing 12.12, libc::SIG_IGN (short for *signal ign*ore) is provided as the signal handler to libc::signal(). The default behavior is reset on line 13. libc::signal() is called again, this time with SIG_DFL (short for *signal default*) as the signal handler.

Listing 12.11 Project metadata for ignore project

```

                                                  Ignores the
 7
       raise(SIGTERM);
                                                  SIGTERM signal
 8
 9
                                      libc::raise() allows code
10
     println!("ok");
                                      to make a signal; in this
11
                                      case, to itself.
    unsafe {
12
13
      signal (SIGTERM, SIG DFL);
                                                       Resets SIGTERM
14
       raise(SIGTERM);
                                                      to its default
                                   Terminates
15
                                   the program
16
```

```
17 println!("not ok");

This code is never reached, and therefore, this string is never printed.
```

12.9 Shutting down from deeply nested call stacks

What if our program is deep in the middle of a call stack and can't afford to unwind? When receiving a signal, the program might want to execute some cleanup code before terminating (or being forcefully terminated). This is sometimes referred to as *nonlocal control transfer*. UNIX-based operating systems provide some tools to enable you to make use of that machinery via two system calls—setjmp and longjmp:

- setjmp sets a marker location.
- longjmp jumps back to the previously marked location.

Why bother with such programming gymnastics? Sometimes using low-level techniques like these is the only way out of a tight spot. These approach the "Dark Arts" of systems programming. To quote the manpage:

"setjmp() and longjmp() are useful for dealing with errors and interrupts encountered in a low-level subroutine of a program."

—Linux Documentation Project: setjmp(3)

These two tools circumvent normal control flow and allow programs to teleport themselves through the code. Occasionally an error occurs deep within a call stack. If our program takes too long to respond to the error, the OS may simply abort the program, and the program's data may be left in an inconsistent state. To avoid this, you can use longjmp to shift control directly to the error-handling code.

To understand the significance of this, consider what happens in an ordinary program's call stack during several calls to a recursive function as produced by the code in listing 12.13. Each call to dive() adds another place that control eventually returns to. See the left-hand side of table 12.3. The longjmp system call, used by listing 12.17, bypasses several layers of the call stack. Its effect on the call stack is visible on the right-hand side of table 12.3.

Table 12.3 Comparing the intended output from listing 12.13 and listing 12.17

```
Listing 12.13 produces a symmetrical pattern.
                                                 Listing 12.17 produces a much different pattern.
Each level is caused by a nested call to dive(),
                                                 After a few calls to dive(), control teleports back
which is removed when the calls return.
                                                 to main() without returning the calls to dive().
##
                                                 ##
###
                                                 ###
####
                                                 early return!
#####
                                                 finishing!
###
##
#
```

On the left side of table 12.3, the call stack grows one step as functions are called, then shrinks by one as each function returns. On the right side, the code jumps directly from the third call to the top to the call stack.

The following listing depicts how the call stack operates by printing its progress as the program executes. The code for this listing is in ch10/ch10-callstack/src/main.rs.

Listing 12.13 Illustrating how the call stack operates

```
1 fn print depth(depth:usize) {
      for in 0..depth {
          print!("#");
 3
 4
      println!("");
 5
 6 }
 8 fn dive(depth: usize, max depth: usize) {
9
     print depth(depth);
10
     if depth >= max depth {
          return:
11
12
      } else {
13
          dive(depth+1, max depth);
15
16
      print depth(depth);
17 }
18
19 fn main() {
      dive(0, 5);
2.0
21 }
```

There's a lot of work to do to make this happen. The Rust language itself doesn't have the tools to enable this control-flow trickery. It needs to access some provided by its compiler's toolchain. Compilers provide special functions known as *intrinsics* to application programs. Using an intrinsic function with Rust takes some ceremony to set up, but that operates as a standard function once the set-up is in place.

12.9.1 Introducing the sjlj project

The sjlj project demonstrates contorting the normal control flow of a function. With the help of some assistance from the OS and the compiler, it's actually possible to create a situation where a function can move to anywhere in the program. Listing 12.17 uses that functionality to bypass several layers of the call stack, creating the output from the right side of table 12.3. Figure 12.5 shows the control flow for the sjlj project.

12.9.2 Setting up intrinsics in a program

Listing 12.17 uses two intrinsics, setjmp() and longjmp(). To enable these in our programs, the crate must be annotated with the attribute provided. The following listing provides this documentation.

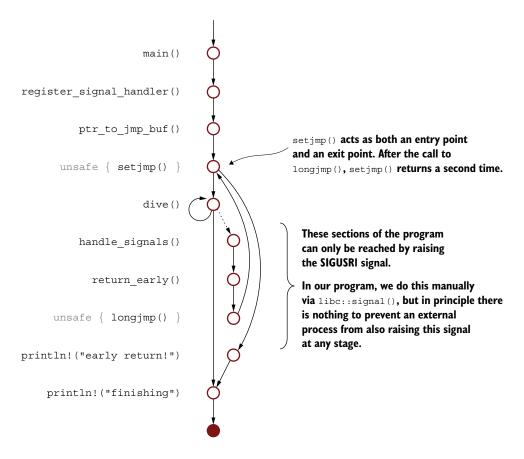

Figure 12.5 Control flow of the sjlj project. The program's control flow can be intercepted via a signal and then resumed from the point of setjmp().

Listing 12.14 Crate-level attribute required in main.rs

#![feature(link llvm intrinsics)]

This raises two immediate questions. We'll answer the following shortly:

- What is an intrinsic function?
- What is LLVM?

Additionally, we need to tell Rust about the functions that are being provided by LLVM. Rust won't know anything about them, apart from their type signatures, which means that any use of these must occur within an unsafe block. The following listing shows how to inform Rust about the LLVM functions. The source for this listing is in ch12/ch12-sjlj/src/main.rs.

Listing 12.15 Declaring the LLVM intrinsic functions within listing 12.17

```
extern "C" {
    #[link_name = "llvm.eh.sjlj.setjmp"]
    pub fn setjmp(_: *mut i8) -> i32;

    #[link_name = "llvm.eh.sjlj.longjmp"]
    pub fn longjmp(_: *mut i8);
}

As we're not using the argument's name, uses
an underscore (_) to make that explicit
Provides specific instructions to the linker about where it should look to find the function definitions
```

This small section of code contains a fair amount of complexity. For example

- extern "C" means "This block of code should obey C's conventions rather than Rust's."
- The link_name attribute tells the linker where to find the two functions that we're declaring.
- The eh in llvm.eh.sjlj.setjmp stands for exception handling, and the sjlj stands for setjmp/longjmp.
- *mut i8 is a pointer to a signed byte. For those with C programming experience, you might recognize this as the pointer to the beginning of a string (e.g., a *char type).

WHAT IS AN INTRINSIC FUNCTION?

Intrinsic functions, generally referred to as intrinsics, are functions made available via the compiler rather than as part of the language. Whereas Rust is largely target-agnostic, the compiler has access to the target environment. This access can facilitate extra functionality. For example, a compiler understands the characteristics of the CPU that the to-be-compiled program will run on. The compiler can make that CPU's instructions available to the program via intrinsics. Some examples of intrinsic functions include

- Atomic operations—Many CPUs provide specialist instructions to optimize certain workloads. For example, the CPU might guarantee that updating an integer is an atomic operation. Atomic here is meant in the sense of being indivisible. This can be extremely important when dealing with concurrent code.
- Exception handling—The facilities provided by CPUs for managing exceptions differ. These facilities can be used by programming language designers to create custom control flow. The setjmp and longjmp intrinsics, introduced later in this chapter, fall into this camp.

WHAT IS LLVM?

From the point of view of Rust programmers, LLVM can be considered as a subcomponent of rustc, the Rust compiler. LLVM is an external tool that's bundled with rustc. Rust programmers can draw from the tools it provides. One set of tools that LLVM provides is intrinsic functions.

LLVM is itself a compiler. Its role is illustrated in figure 12.6.

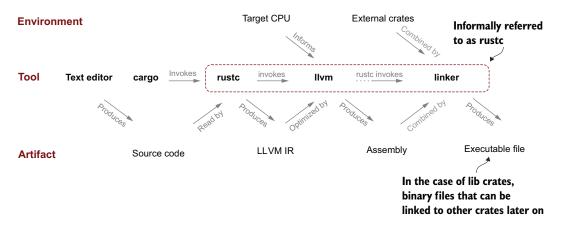

Figure 12.6 Some of the major steps required to generate an executable from Rust source code. LLVM is an essential part of the process but not one that is user-facing.

LLVM translates code produced by rustc, which produces LLVM IR (intermediate language) into machine-readable assembly language. To make matters more complicated, another tool, called a linker, is required to stitch multiple crates together. On Windows, Rust uses link.exe, a program provided by Microsoft as its linker. On other operating systems, the GNU linker 1d is used.

Understanding more detail about LLVM implies learning more about rustc and compilation in general. Like many things, getting closer to the truth requires exploring through a fractal-like domain. Learning every subsystem seems to require learning about another set of subsystems. Explaining more here would be a fascinating, but ultimately distracting diversion.

12.9.3 Casting a pointer to another type

One of the more arcane parts of Rust's syntax is how to cast between pointer types. You'll encounter this as you make your way through listing 12.17. But problems can arise because of the type signatures of setjmp() and longjmp(). In this code snippet, extracted from listing 12.17, you can see that both functions take a *mut i8 pointer as an argument:

```
extern "C" {
    #[link_name = "llvm.eh.sjlj.setjmp"]
    pub fn setjmp(_: *mut i8) -> i32;

#[link_name = "llvm.eh.sjlj.longjmp"]
    pub fn longjmp(_: *mut i8);
}
```

Requiring a *mut i8 as an input argument is a problem because our Rust code only has a reference to a *jump buffer* (e.g., &jmp_buf).² The next few paragraphs work through the process of resolving this conflict. The jmp buf type is defined like this:

```
const JMP_BUF_WIDTH: usize =
  mem::size_of::<usize>() * 8;

type jmp_buf = [i8; JMP_BUF_WIDTH];
This constant is 64 bits wide (8 × 8
bytes) in 64-bit machines and 32 bits
wide (8 × 4 bytes) on 32-bit machines.
```

The jmp_buf type is a type alias for an array of i8 that is as wide as 8 usize integers. The role of jmp_buf is to store the state of the program, such that the CPU's registers can be repopulated when needed. There is only one jmp_buf value within listing 12.17, a global mutable static called RETURN_HERE, defined on line 14. The following example shows how jmp_buf is initialized:

```
static mut RETURN_HERE: jmp_buf = [0; JMP_BUF_WIDTH];
```

How do we treat RETURN_HERE as a pointer? Within the Rust code, we refer to RETURN_HERE as a reference (&RETURN_HERE). LLVM expects those bytes to be presented as a *mut i8. To perform the conversion, we apply four steps, which are all packed into a single line:

```
unsafe { &RETURN_HERE as *const i8 as *mut i8 }
```

Let's explain what those four steps are:

- 1 Start with &RETURN_HERE, a read-only reference to a global static variable of type [i8; 8] on 64-bit machines or [i8; 4] on 32-bit machines.
- 2 Convert that reference to a *const i8. Casting between pointer types is considered safe Rust, but deferencing that pointer requires an unsafe block.
- 3 Convert the *const i8 to a *mut i8. This declares the memory as mutable (read/write).
- 4 Wrap the conversion in an unsafe block because it deals with accessing a global variable.

Why not use something like &mut RETURN_HERE as *mut i8? The Rust compiler becomes quite concerned about giving LLVM access to its data. The approach provided here, starting with a read-only reference, puts Rust at ease.

12.9.4 Compiling the sjlj project

We're now in a position where possible points of confusion about listing 12.17 should be minor. The following snippet again shows the behavior we're attempting to replicate:

² jmp_buf is the conventional name for this buffer, which might be useful for any readers who want to dive deeper themselves.

```
$ git clone https://github.com/rust-in-action/code rust-in-action
$ cd rust-in-action/ch12/ch12-sjlj
$ cargo run -q
#
#
early return!
finishing!
```

One final note: to compile correctly, the sjlj project requires that rustc is on the nightly channel. If you encounter the error "#![feature] may not be used on the stable release channel," use rustup install nightly to install it. You can then make use of the nightly compiler by adding the +nightly argument to cargo. The following console output demonstrates encountering that error and recovering from it:

12.9.5 sjlj project source code

The following listing employs LLVM's compiler to access the operating system's long-jmp facilities. longjmp allows programs to escape their stack frame and jump anywhere within their address space. The code for listing 12.6 is in ch12/ch12-sjlj/Cargo.toml and listing 12.17 is in ch12/ch12-sjlj/src/main.rs.

Listing 12.16 Project metadata for sjlj

```
[package]
name = "sjlj"
version = "0.1.0"

Summary 417

12.10 A note on applying these techniques to platforms without signals

Signals are a "UNIX-ism." On other platforms, messages from the OS are handled differently. On MS Windows, for example, command-line applications need to provide a handler function to the kernel via SetConsoleCtrlHandler. That handler function is then invoked when a signal is sent to the application.

Regardless of the specific mechanism, the high-level approach demonstrated in this chapter should be fairly portable. Here is the pattern:

- Your CPU generates interrupts that require the OS to respond.
- Operating systems often delegate responsibility for handling interrupts via some sort of callback system.
- A callback system means creating a function pointer.

12.11 Revising exceptions

At the start of the chapter, we discussed the distinction between signals, interrupts, and exceptions. There was little coverage of exceptions, directly. We have treated these as a special class of interrupts. Interrupts themselves have been modeled as signals.

To wrap up this chapter (and the book), we explored some of the features available in rustc and LLVM. The bulk of this chapter utilized these features to work with signals. Within Linux, signals are the main mechanism that the OS uses to communicate with applications. On the Rust side, we have spent lots of time interacting with libc and unsafe blocks, unpacking function pointers, and tweaking global variables.

Summary

- Hardware devices, such as the computer's network card, notify applications about data that is ready to be processed by sending an interrupt to the CPU.
- Function pointers are pointers that point to executable code rather than to data. These are denoted in Rust by the fn keyword.
- Unix operating systems manage job control with two signals: SIGSTOP and SIGCONT.
- Signal handlers do the least amount of work possible to mitigate the risk of triggering race conditions caused when multiple signal handlers operate concurrently. A typical pattern is to set a flag with a global variable. That flag is periodically checked within the program's main loop.
- To create a global variable in Rust, create a "mutable static." Accessing mutable statics requires an unsafe block.
- The OS, signals, and the compiler can be utilized to implement exception handling in programming languages via the setjmp and longjmp syscalls.
- Without the unsafe keyword, Rust programs would not be able to interface effectively with the OS and other third-party components.

Rust IN ACTION

Tim McNamara

ust is the perfect language for systems programming. It delivers the low-level power of C along with rock-solid safety features that let you code fearlessly. Ideal for applications requiring concurrency, Rust programs are compact, readable, and blazingly fast. Best of all, Rust's famously smart compiler helps you avoid even subtle coding errors.

Rust in Action is a hands-on guide to systems programming with Rust. Written for inquisitive programmers, it presents real-world use cases that go far beyond syntax and structure. You'll explore Rust implementations for file manipulation, networking, and kernel-level programming and discover awesome techniques for parallelism and concurrency. Along the way, you'll master Rust's unique borrow checker model for memory management without a garbage collector.

What's Inside

- Elementary to advanced Rust programming
- Practical examples from systems programming
- Command-line, graphical and networked applications

For intermediate programmers. No previous experience with Rust required.

Tim McNamara uses Rust to build data processing pipelines and generative art. He is an expert in natural language processing and data engineering.

- "This well-written book will help you make the most of what Rust has to offer."
 - —Ramnivas Laddad author of *AspectJ in Action*
- "Engaging writing style and crisp, easy-to-grasp examples help the reader get off the ground in no time."
 - -Sumant Tambe, Linkedin
 - **Rust in Action is remarkably polished!**
 - —Christopher Haupt, Swoogo
 - "Makes it easy to explore the language and get going with it."
 - —Federico Hernandez Meltwater
 - GI highly recommend this book to those who want to learn Rust.
 - —Afshin Mehrabani, Etsy
